

Identification in Macroeconomics

Emi Nakamura and Jón Steinsson*

Columbia University

April 18, 2018

Abstract

This paper discusses empirical approaches macroeconomists use to answer questions like: What does monetary policy do? How large are the effects of fiscal stimulus? What caused the Great Recession? Why do some countries grow faster than others? Identification of causal effects plays two roles in this process. In certain cases, progress can be made using the direct approach of identifying plausibly exogenous variation in a policy and using this variation to assess the effect of the policy. However, external validity concerns limit what can be learned in this way. Carefully identified causal effects estimates can also be used as moments in a structural moment matching exercise. We use the term “identified moments” as a short-hand for “estimates of responses to identified structural shocks,” or what applied microeconomists would call “causal effects”. We argue that such identified moments are often powerful diagnostic tools for distinguishing between important classes of models (and thereby learning about the effects of policy). To illustrate these notions we discuss the growing use of cross-sectional evidence in macroeconomics and consider what the best existing evidence is on the effects of monetary policy.

We would like to thank Joshua Angrist, John Cochrane, Gregory Cox, Gauti Eggertsson, Adam Guren, Jonathon Hazell, Juan Herreño, Ethan Ilzetzki, Alisdair McKay, Edward Nelson, Serena Ng, Mikkel Plagborg-Møller, Valerie Ramey, David Romer, David Thesmar, Jonathan Vogel, Johannes Wieland, Christian Wolf, and Michael Woodford for valuable comments and discussions. We thank the National Science Foundation (grant SES-1056107) and the Alfred P. Sloan Foundation for financial support.

1 Introduction

Any scientific enterprise needs to be grounded in solid empirical knowledge about the phenomenon in question. Milton Friedman put this well in his Nobel lecture in 1976: “In order to recommend a course of action to achieve an objective, we must first know whether that course of action will in fact promote the objective. Positive scientific knowledge that enables us to predict the consequences of a possible course of action is clearly a prerequisite for the normative judgment whether that course of action is desirable.”

Many of the main empirical questions in macroeconomics are the same as they were 80 years ago when macroeconomics came into being as a separate sub-discipline of economics in the wake of the Great Depression. These are questions such as: What are the sources of business cycle fluctuations? How does monetary policy affect the economy? How does fiscal policy affect the economy? Why do some countries grow faster than others? Those new to our field or viewing it from afar may be tempted to ask: How can it be that after all this time we don't know the answers to these questions?

The reason is that identification in macroeconomics is difficult. Take the case of monetary policy. To be able to accumulate direct positive knowledge about the effects of monetary policy on the economy, we need exogenous variation in monetary policy. Unfortunately for us as empirical scientists, the Federal Reserve does not randomize when setting interest rates. Quite to the contrary, the Federal Reserve employs hundreds of PhD economists to pore over every little bit of incoming data about the economy so as to make monetary policy as endogenous as it possibly can be. Indeed, the main purpose of the Federal Reserve is to vary monetary policy in a way that reacts to other developments that are affecting output and inflation. This fact, of course, makes our lives as empirical macroeconomists very difficult. Quite a bit of ingenuity and careful research is required to identify a component of monetary policy that is plausibly exogenous to the main outcome variables of interest such as future output and inflation.

This challenge can most clearly be seen by considering an example. The Federal Reserve lowered interest rates aggressively in 2008 as evidence mounted that the economy was heading for a severe downturn. Suppose one sought to use this variation in monetary policy to estimate the effect of monetary policy on the economy by estimating an OLS regression of the change in output on the change in interest rates. Doing this might lead one to conclude that reductions in interest rates lead to *decreases* in output. Would this constitute convincing evidence on the effects of monetary policy? Of course not. The reason the Fed was lowering interest rates was because other

factors—such as rapidly falling home prices and their effects on the balance sheets of households, firms, and banks—were negatively affecting the economy. In a simple OLS regression, these other factors would confound the effects of the change in monetary policy. This approach would, therefore, uncover not the pure effect of the interest rate reduction, but rather, the combined effect of the interest rate reduction and the adverse macroeconomic factors that led the Fed to undertake it.¹

The challenging nature of identification in macroeconomics as well as the modest number of data points macroeconomists typically have to work with has meant that macroeconomists have attempted an eclectic approach to identification. As wars between the forces of structural and non-structural methods have raged in applied microeconomics, empirical macroeconomists have borrowed from both camps but also advanced ideas that in some cases seem puzzling or even downright backwards to empirical researchers outside our field. In our view, this eclectic approach has served our field well and while empirical macroeconomists still have much to learn from their colleagues in applied microeconomics, we feel that applied microeconomists could also learn a few things from our approach to identification.

An important strand of empirical work in macroeconomics attempts the challenging task of identifying plausibly exogenous variation in macroeconomic policy and using this variation to assess the effects of the policy. We refer to this type of work as direct causal inference. The approaches macroeconomists use are by and large similar to the work-horse methods of applied microeconomics. The analysis looks a bit different in macroeconomics mainly because of the greater importance of dynamics. In section 4, we provide a critical assessment of how several of the main methods of direct causal inference including identified VARs are used in macroeconomics. We do this in the context of asking what the best available evidence is on monetary non-neutrality.

A serious challenge faced by researchers attempting direct causal inference in macroeconomics is that the natural experiments we can identify in the data are rarely exactly the experiments we would need to answer the policy questions we are interested in. This “external validity” problem can be illustrated by thinking about monetary and fiscal policy. One such issue is that the dynamic nature of monetary and fiscal policy makes these policies very high dimensional. Some monetary policy announcements only affect expectations about policy in the very short run (e.g., will the Fed tighten this month or next month), while others affect policy expectations both in the short run and longer run, and still others only affect expectations about policy several years in the future (e.g., when policy is at the zero lower bound and the Fed makes a commitment to keep it there for

¹An analogous argument can be made regarding the fiscal stimulus that was enacted during the Great Recession.

longer than previously expected). The same is true of fiscal policy. The recent theoretical literature has emphasized that the degree of persistence and more generally the future time profile of a policy action greatly affects its impact on current output and inflation.²

A second external validity issue is that the effects of fiscal shocks depend on the response of monetary policy (i.e., whether it is constrained by the zero-lower-bound) and the response of tax policy (i.e., whether a war is financed with a sharp contemporary increase in taxes or with debt that is whittled down over many subsequent years). The effects of monetary policy, of course, also depend on the response of fiscal and tax policies. A third issue is that the effects of monetary and fiscal policy may differ depending on the level of slack in the economy and various other characteristics of the economy, such as how open it is. A fourth issue is that the degree to which a policy action is a surprise can affect both how strongly and when the economy reacts to it.

These external validity issues (and others) mean that even very cleanly identified monetary and fiscal natural experiments, at best, give us a partial assessment of how *future* monetary and fiscal policy actions will affect the economy. One response to these issues is to simply gather direct causal evidence about each and every different case. This may, however, not be feasible. And even if it is feasible, it seems that one should be able to learn something about one case from evidence on another.

Due to the challenges described above, much empirical work in macroeconomics is more structural in nature. Such work often takes the form of researchers identifying a set of moments in the data and arguing that these moments can discriminate between different models of how the economy works. Estimates of causal effects (i.e., the response to identified structural shocks) can play an important role in this type of inference. They can be viewed as target moments models should match in much the same way as unconditional means, variances, and covariance. We use the term “identified moments” as a short-hand for “estimates of responses to identified structural shocks”—what applied microeconomists would call “causal effects.”³ We argue that identified moments are often particularly informative moments for distinguishing between important classes of macroeconomic models.

Consider the case of distinguishing between Real Business Cycle (RBC) models and New Key-

²For example, a highly persistent monetary policy shock has much larger effects on current output and inflation than a transitory shock. Standard models also imply that news about a future monetary policy action of equal magnitude (in terms of its effect on real interest rates) has larger effects if the news is about policy further in the future.

³The term “identified moments” may seem odd to some. In econometrics, it is parameters that are identified, not moments. We use the term “moment” in a broad sense to refer to a target statistic that a researcher wants his or her model to match. We use the term “identified” because the target statistics we have in mind are estimates of causal effect parameters—or what macroeconomists would call estimated responses to “identified structural shocks”—as opposed to simple unconditional moments such as means, variances and covariances.

nesian models which is important for many policy questions. One approach is to use full information structural estimation methods such as maximum likelihood or Bayesian methods. Another approach is to match unconditional means, variances, and covariances in the tradition of the RBC calibration literature. In contrast, [Rotemberg and Woodford \(1997\)](#) and [Christiano, Eichenbaum, and Evans \(2005\)](#) estimate the response of output and inflation to identified monetary policy shocks and use these responses to discriminate between different business cycle models. Similarly, [Gali \(1999\)](#) and [Basu, Fernald, and Kimball \(2006\)](#) use the response of output and hours to identified productivity shocks to distinguish between models.

Another example is the recent literature on regional fiscal multipliers, and more generally the growing literature that aims to shed light on macroeconomic questions using cross-sectional identification strategies. Estimates of the regional government spending multiplier do not *directly* answer the policy question macroeconomists are most interested in the effect of fiscal stimulus at the national level. However, the regional fiscal multiplier turns out to have a great deal of power in distinguishing between different models of the business cycle ([Nakamura and Steinsson, 2014](#)). Models that can match a large regional multiplier typically imply that output responds strongly to demand shocks. In these models the aggregate multiplier is large when monetary policy is accommodative, e.g., at the zero lower bound. For this reason, the recent literature on the regional fiscal multiplier has been able to provide powerful indirect evidence on the effectiveness of aggregate fiscal stimulus.

A third example is the use of estimates of the marginal propensity to consume (MPC) from a transitory fiscal rebate to distinguish between competing models of consumption dynamics. Recent work has used truly random variation in the timing of fiscal stimulus checks to estimate a quarterly MPC of roughly 0.25 for non-durable consumption (see, e.g., [Johnson, Parker, Souleles, 2006](#); [Parker et al., 2013](#)). [Kaplan and Violante \(2014\)](#) use these estimates to distinguish between competing models of consumption dynamics. Their favored model adds illiquid assets that earn high returns to an otherwise standard model with uninsurable income risk and borrowing constraints. [Angeletos et al. \(2001\)](#) argue that models in which households face self-control problems can help match the estimated MPC in the data.

The use of identified moments as in the examples above is typically controversial since the favored interpretation of these moments typically depends on identifying assumptions. So, why do it? What is the upside of this approach relative to, for example, targeting simple unconditional moments? An important advantage is that the ability of a model to match identified moments typically depends on a particular sub-block of the model and is often insensitive to model mis-

specification in other sub-blocks of the model. In the examples above, one does not, for example, have to take a stand on whether business cycles are driven by demand or supply shocks. In contrast, inference based on unconditional moments is typically highly sensitive to this. Moreover, [Kaplan and Violante's \(2014\)](#) inference based on the MPC is unlikely to be sensitive to what of frictions are included in the model outside of the consumption block, for example, price or wage rigidity, or investment and labor adjustment costs. This means it is possible to learn about the consumption features of the economy independently from these other features.⁴

The state of empirical macroeconomics is frequently critiqued. These critiques tend to focus on battles of decades past. Our view is much more positive. There has been a great deal of growth in empirical macroeconomics over the past decade or so with new approaches being used and the standards for identification rising rapidly. A particularly exciting development has been the growing literature estimating what we call identified moments and relating them to fully formed general equilibrium structural models. This growing synergy between well identified empirical work and serious theoretical work has the potential to advance our knowledge about the core questions in macroeconomics substantially.

The rest of this article is organized as follows. Section 2 discusses the value of identified moments in structural estimation. It also discusses the distinction between micro moments and macro moments and the value of coming up with portable statistics. Section 3 discusses the growing use of cross-sectional identification strategies in macroeconomics. A key issue is how to go from cross-sectional moments to aggregate implications. In this context, we survey the empirical literature on the government spending multiplier. Section 4 provides a critical assessment of methods used for direct causal inference in macroeconomics. We discuss VARs in detail (including the use of external instruments), but we also discuss the use of large shocks, the narrative record, and discontinuity-based identification. We do this in the context of surveying the empirical literature on monetary non-neutrality.

2 The Power of Portable Statistics

One of the important innovative features of the early RBC literature was a move away from using likelihood-based empirical methods towards empirical evaluation based on matching moments

⁴Our argument for moment matching using identified moments moments is related to [Chetty's \(2009\)](#) argument for sufficient statistics. Our emphasis is, however, on using the identified moments to distinguish between models, i.e., learn about deep structural parameters. The hope is that these structural parameter estimates will help answer many policy questions. Chetty's emphasis is on combining identified moments into a formula (a "sufficient statistic") that answers a particular policy question.

(Kydland and Prescott, 1982; Prescott, 1986).⁵ An advantage of this approach is that it leads to the creation of “portable statistics” that can be used over and over again by researchers to discipline and test models. This allows for a division of labor and a fruitful back-and-forth between the theoretical and empirical parts of the field (and other fields).⁶ The equity premium is a good example of a portable statistic.⁷ Mehra and Prescott (1985) consider whether the equity premium is consistent with one specific class of models. A generation of subsequent researchers has then used this same statistic to evaluate a host of new models. The result has been an enormously influential literature on the nature of risk and risk aversion.

2.1 Micro and Macro Moments

It is useful to distinguish between several different types of moments that have been influential in empirical macroeconomics. One distinction is between “micro moments” and “macro moments”. Micro moments are constructed using microeconomic data on the behavior of individuals and firms. A prominent example is the frequency of price change and related statistics on price rigidity (Bils and Klenow, 2004; Nakamura and Steinsson, 2008; Klenow and Kryvtsov, 2008). These statistics help discipline models designed to understand the effects of monetary policy on the economy. The fact that prices change infrequently provides evidence for the key friction in such models. Another prominent example is the change in time spent shopping as well as the quantity and quality of food intake at the time of retirement (Aguiar and Hurst, 2005). These statistics help distinguish between competing life-cycle models of household consumption and savings behavior.

Macro moments use aggregated data to identify equilibrium outcomes that are informative about what type of world we live in. The equity premium is an example of a highly influential macro moment. Another example is facts about changes in real wages and hours worked per person over the past century. The fact that real wages have risen by a large amount while hours worked have been stable or fallen slightly strongly rejects models without income effects on labor

⁵This literature also adopted an informal approach to estimation which is often referred to as calibration. Calibration is simply informal GMM or SMM without standard errors. Macroeconomists tend to be more worried about “model error” than sampling error compared to researchers in some other subfields of economics (e.g., IO). We therefore tend to use a larger share of our computational budget on exploring the model space than on computing standard errors, relative to researchers in these other subfields.

⁶On this point, our argument is similar to Summers (1991).

⁷What is an example of a statistic that is not portable? The score of the likelihood function of a particular model (the moment maximum likelihood estimation seeks to match) is very informative about that particular model. But it is not a very intuitive statistic to use to evaluate other models and is rarely (if ever) reused as a moment that other researchers (with other models) seek to match.

supply and, in fact, suggests that income effects are slightly larger than substitution effects in the long run. This motivates the use of “balanced growth preferences” in macroeconomic models (King, Plosser, and Rebelo, 1988; Boppart and Krusell, 2016).

There is a rich tradition in macroeconomics of using simple micro and macro moments to make inference about how the world works. In many cases, these types of statistics can yield powerful inference. Prominent examples in addition to those discussed above include the RBC literature (Kydland and Prescott, 1982; King and Rebelo, 1999), the Shimer puzzle literature (Shimer, 2005), the misallocation literature (Hsieh and Klenow, 2009), the literature on exchange rate disconnect (Meese and Rogoff, 1983; Itskhoki and Mukhin, 2017), and the literature on “wedges” (Chari, Kehoe, and McGrattan, 2008; Shimer, 2009).

2.2 Causal Effects as Identified Moments

A second distinction is between what we call “identified moments” and simpler moments. Our idea in making this distinction is to contrast simple statistics such as means, variances, and correlations, with more complex statistics that are derived from empirical strategies designed to uncover what applied microeconomists would call causal effects but macroeconomists would call responses to structural shocks. The last quarter century has seen a “revolution of identification” in many applied fields of economics (Angrist and Pischke, 2010). This revolution has increased emphasis on identifying causal effects using credible research designs based on the use of instrumental variables, difference-in-difference analysis, regression discontinuities, and randomized controlled trials. It is these types of causal effects estimates that we refer to as identified moments.

In some cases, identified moments correspond directly to a particular deep structural parameter. For example, there is a large literature in labor economics that estimates the labor supply elasticity (see, e.g., Chetty, 2012; Chetty et al., 2013). Macroeconomists have long made use of causal effects estimates of this kind to discipline the models that they work with. In the jargon of macroeconomics, we frequently “calibrate” certain parameters of our models (such as the labor supply elasticity) based on external estimates.

Many identified moments, however, do not correspond directly to a deep structural parameter. Two prominent examples we discuss in the introduction are estimates of the MPC out of a transitory fiscal rebate and estimates of the regional fiscal multiplier. In these cases, a theoretical framework is required to go from the identified moment to the macroeconomic questions of inter-

est. These types of identified moments are valuable because they can be used as empirical targets in a structural moment matching exercise aimed at distinguishing between competing models of the world which differ in their implications about the macroeconomic question of interest.⁸

There is a prevalent view in macroeconomics that if your empirical strategy is to calculate the same moment in real-world data as in data from a set of models, you might as well focus on very simple unconditional moments. A moment is a moment, the argument goes. Relative to simple unconditional moments, the advantage of identified moments is that they can provide evidence on specific causal mechanisms of a model, and may be relatively invariant to other model features.

Consider the recent debate on the role of changes in house prices in causing the Great Recession of 2007-2009. [Mian, Rao, and Sufi \(2013\)](#) and [Mian and Sufi \(2014\)](#) seek to shed light on these questions by comparing changes in consumption and employment in cities that experienced large house price changes with cities that experienced smaller house price changes. An important empirical challenge is that causation may run both ways: increases in house prices may stimulate economic activity, but a local boom may also increase house prices. The raw correlation between changes in house prices and economic activity will be due to both effects. To isolate the causal effect of house prices on consumption and employment, Mian et al. propose to instrument for changes in house prices with estimates of housing supply elasticities constructed by [Saiz \(2010\)](#). The idea for identification is that national shocks will lead house prices to increase more in cities where housing supply is less elastic.⁹

Using this identification strategy, [Mian, Rao, and Sufi \(2013\)](#) find that the elasticity of consumption with respect to housing net worth is 0.6 to 0.8, while [Mian and Sufi \(2014\)](#) find that the elasticity of non-tradable employment with housing net worth is 0.37. These estimates do not directly answer the macroeconomic question of how much aggregate house prices affect economic activity since Mian et al.'s empirical approach is based on comparing one city to another and therefore "differences out" aggregate general equilibrium effects.¹⁰ The empirical value of Mian

⁸Formally, the idea is to use indirect inference with limited information empirical models designed to estimate causal effects (e.g., an instrumental variables regression, a difference-in-difference design, or a regression-discontinuity design) as auxiliary models. See [Smith \(2008\)](#) for an introduction to indirect inference.

⁹[Saiz's \(2010\)](#) estimate of the housing supply elasticity is constructed based on data on city topology and land-use regulation. It is obviously not randomly assigned (for example, land availability is correlated with whether a city is on the coast). However, the argument for identification, like in many natural experiments, is that whatever makes these coastal (and otherwise land constrained) locations different does not affect their response to aggregate shocks directly, except for through the implications for the housing market.

¹⁰The the whole question of how house prices affect consumption and employment many strike some macroeconomists as being ill-posed. In general equilibrium, house prices are an endogenous variable. They respond to various exogenous disturbances, which may affect consumption directly (as opposed to only through house prices). However, since Mian et al.'s estimates focus on the cross-sectional relationship between house prices and economic activity and thereby difference out aggregate general equilibrium effects. In some simple cases, it is possible to show that this type

et al.'s estimates is that they are quite informative about the “consumption block” of macroeconomic models. They strongly reject simple complete markets models of consumption such as the influential model of [Sinai and Souleles \(2005\)](#)—in which the elasticity of consumption to house prices is zero—in favor of models with life-cycle effects, uninsurable income risk, borrowing constraints, and in which households can substitute away from housing when its price rises (see, e.g., [Berger et al. \(2017\)](#) for a discussion of such a model). This latter class of models has quite different implications about the effects of macroeconomic policies such as fiscal and monetary policy—but also housing policy—than the former class of models.¹¹

The identification strategy used by [Mian, Rao, and Sufi \(2013\)](#) and [Mian and Sufi \(2014\)](#) is by no means uncontroversial, as is often the case with identified moments. A much simpler alternative empirical approach would be to consider instead the raw correlation between house prices and consumption or house prices and employment. However, a downside of focusing on these simple moments is that their value in a model is likely to be sensitive to assumptions that have little to do with consumption behavior, such as what shocks drive the business cycle, and to the strength of general equilibrium effects, such as the response of prices and wages to demand shocks (which, in turn, may depend on virtually everything about how the model works). In other words, using these simple moments results in a joint test of all the parameters and assumptions in the model, while identified moments can focus in on the consumption block of the model and provide inference that is robust to the specification of other parts of the model.¹²

Another prominent example of an identified moment matching exercise is recent work that seeks to determine the role of unemployment insurance (UI) extensions in delaying recovery from the Great Recession. During this recession, temporary federal programs raised the duration of UI benefits from 26 weeks to 99 weeks in some states, and an important policy question is the extent to which this led to reduced job search effort by households and reduced job posting by employ-

of cross-sectional instrumental variables regression is equal to the partial equilibrium response of consumption to a change in house prices or the response to a foreign housing demand shock (see [Guren et al., 2017](#)). More generally, these estimates must be interpreted through the lens of a fully formed general equilibrium model.

¹¹[Midrigan and Philippon \(2016\)](#) use evidence similar to that of [Mian and Sufi \(2014\)](#) to pin down key parameters of a household liquidity model. They use the model to argue that household deleveraging cannot explain the large drop in employment during the Great Recession because its effect on the natural rate of interest is too small.

¹²Similar methods have been applied to assess the importance of financial frictions on firms. [Catherine et al. \(2017\)](#) use IV estimates of the response of firm investment to changes in real estate collateral to pin down parameters in a structural model with financial friction and then use the model to quantify the aggregate effects of relaxing collateral constraints. [Chodorow-Reich \(2014\)](#) uses bank shocks to identify the effects of financial constraints on firm employment. In the appendix to his paper, he uses these micro-level estimates pin down parameters in a general equilibrium model of the effect of bank shocks on the economy as a whole. [Huber \(2017\)](#) estimates direct and indirect firm effects as well as regional effects of a large bank shock in Germany. Other important papers in this literature include [Peek and Rosengren \(2000\)](#), [Calomiris and Mason \(2003\)](#), [Ashcraft \(2005\)](#), [Greenstone et al. \(2015\)](#), [Mondragon \(2017\)](#).

ers. [Hagedorn, Manovskii, and Mitman \(2015\)](#) and [Chodorow-Reich, Cogleianese, and Karabarbounis \(2017\)](#) estimate the response of unemployment to variation in UI benefit extensions across states (the former paper uses discontinuity based identification, while the latter uses an instrumental variables approach). They then use these cross-sectional identified moments to determine key parameters in a labor market search model and use the resulting model to determine how UI extensions will affect the economy at the aggregate level. Here, again, it is likely possible to pin down these same parameters using simple moments (such as the variance and covariance of unemployment, vacancies, wages, and benefit extensions) in a fully specified structural model. However, such an exercise would likely be sensitive to many auxiliary features of the model being used outside the “labor market block” of the model.

Notice that in the examples above, the identified moments give us information primarily on a particular “block” or mechanism of a macroeconomic model. This “piecemeal” form of inference will, therefore, result in partial identification of the model space. It is inevitable that any given statistic or set of statistics will not be able to pick out a single model and reject all others. The fact that several models are consistent with a statistic is not grounds for rejecting the statistic as being uninteresting. We should instead think in reverse: If a statistic has power to reject an important set of models in favor of another set of models, this makes that statistic useful.

3 Aggregate Versus Cross-Sectional Identification

The increased use of cross-sectional identification approaches has been an exciting development in empirical macroeconomics over the past several years. In this work, researchers use geographically disaggregated panel data sets—often disaggregated to the state or metropolitan statistical area level—to identify novel causal effects. The use of regional data typically multiplies the number of data points available by an order of magnitude or more. It also allows for difference-in-difference identification and makes possible the use of a powerful class of instrumental variables: differential regional exposure to aggregate shocks. Prominent examples of this approach include [Mian and Sufi’s \(2014\)](#) work on the role of the housing net worth channel in the Great Recession, [Autor, Dorn, and Hanson’s \(2013\)](#) work on the effects of Chinese imports on US employment over the past two decades, [Beraja, Hurst, and Ospina’s \(2016\)](#) work on wage rigidity during the Great Recession, [Martin and Philippon’s \(2017\)](#) work on the effects of debt on the Great Recession in the Eurozone, [Carvalho et al.’s \(2016\)](#) work on supply chain disruptions after the Great East Japan Earthquake of 2011, and a large literature on fiscal stimulus discussed below.

A key challenge for this literature is how to translate regional responses into aggregate responses. A common approach is to add up regional responses with the implicit assumption that the least affected region is unaffected by the shock and report this sum as the aggregate response. This approach is typically invalid since it ignores general equilibrium effects that influence the aggregate response but are absorbed by time fixed effects in the cross-sectional regressions used in this literature. As an example, Mian and Sufi show that the dramatic fall in house prices between 2006 and 2009 did not *differentially* affect tradables employment in areas with larger house price declines. However, this does not mean that this shock had no effect on tradables employment in the aggregate. (To be clear, they don't make any such claim.) Typically, regional responses can only be translated into aggregate responses through the lens of a fully specified general equilibrium model (see, e.g., [Nakamura and Steinsson, 2014](#)).

Since an aggregate response is usually the object of most direct interest, a common critique of estimates based on cross-sectional identification is that they don't answer the right question. While it is true that these estimates don't *directly* answer the question of interest, they often provide a great deal of indirect evidence regarding this question. The way in which they do this is by helping researchers discriminate between different theoretical views of how the world works. In the language of section 2, these cross-sectional estimates are examples of identified macro moments. They can be used as moments in a moment-matching exercise that is aimed at distinguishing between important classes of general equilibrium structural models of the economy that have different implications about the primary question of interest. This kind of combination of theory and empirics can yield very powerful inference. The literature on the stimulative effects of government spending provides a nice case study to illustrate these ideas.

3.1 Fiscal Stimulus: Aggregate Evidence

Direct aggregate evidence on the government spending multiplier is far from conclusive. This evidence largely comes in two forms: 1) evidence from wars, and 2) evidence from VARs. [Barro and Redlick \(2011\)](#) regress changes in output on changes in defense spending and a few controls for a US sample period including several major wars. Their main conclusion is that the government purchases multiplier is between 0.6 and 0.7. Virtually all of the identification comes from the major wars in their sample (WWI, WWII, and to a lesser extent the Korean War). When they restrict attention to data from after the Korean War, the confidence interval for their estimate includes all remotely plausible values.

Barro and Redlick assume that war-related defense spending is exogenous to output. Conceptually, this is like using wars as an instrument for spending. The strength of this approach is that reverse causation is not likely to be a problem. WWI, WWII, and the Korean War did not happen because the US was in a recession or a boom. However, for war-related spending to be exogenous, it must be that wars only affect output through spending. This is unlikely to be true. Barro and Redlick are aware of this and discuss some of the main potential confounding factors. Two important confounding factors are patriotism and war-time controls on the economy such as rationing and price controls. Patriotism likely increased labor supply during major wars such as WWI and WWII. It therefore potentially results in an upward bias of the multiplier. On the other hand, war-time controls such as rationing and price controls likely result in a downward bias. The overall direction of bias is unclear. Barro and Redlick argue that patriotism is likely the dominant bias, while [Hall \(2009\)](#) argues that the effects of war-time controls result in a net downward bias.

[Blanchard and Perotti \(2002\)](#) regress government spending on four quarterly lags of itself, taxes, output, a quadratic time trend, and a dummy variable for 1975:2.¹³ They view the residual from this regression as exogenous shocks to government spending and construct an impulse response function for output, consumption, and other variables to the government spending shocks by iterating forward a VAR.¹⁴ Their baseline sample period is 1960-1997. They highlight a peak response of output of 1.29 times the initial response of spending. This response occurs 15 quarters after the impulse (after the VAR response of output has swung up, then down, then back up). Unfortunately, they do not report an estimate of the cumulative response of output divided by the cumulative response of spending, which would be more informative.¹⁵

Blanchard and Perotti's approach to identification makes the strong assumption that controlling for four lags of taxes, spending, and output eliminates all endogenous variation in spending. (See section 4 for a more detailed discussion of VAR identification.) They argue that this approach is more likely to be valid than in the case of monetary policy because output stabilization is not as dominant a concern of fiscal policy and because implementation lags are longer in fiscal policy. [Ramey \(2011\)](#) argues, however, that Blanchard and Perotti miss an important part of the response to fiscal shocks because news about fiscal shocks—especially those associated with major wars—

¹³The dummy variable is included due to a large temporary tax cut in 1975:2. They allow for quarter dependence of the coefficients in their VAR. They also consider a version estimated in differences.

¹⁴This is equivalent to performing a Cholesky decomposition of the reduced form errors from the VAR with government spending ordered first.

¹⁵[Ramey \(2016\)](#) and [Ramey and Zubairy \(2017\)](#) provide multiplier estimates of this kind for the Blanchard and Perotti shocks as well as novel defense news shocks for a somewhat longer simple period. These estimates are substantially below one.

arrive well ahead of the main increase in spending.¹⁶ A different concern with Blanchard and Perotti's estimates is lack of precision. Their results come with standard errors so large that few interesting hypotheses can be rejected.¹⁷ Also, their estimates are highly sensitive to the sample period and to which controls are included (Gali et al., 2007). For example, including the Korean War yields substantially lower estimates.

For the purposes of guiding policy, the most serious weakness of the literature discussed above is, however, arguably the fact that these estimates are not very informative about the effectiveness of fiscal stimulus in a deep recession when monetary policy is constrained by the zero lower bound on nominal interest rates. In normal times, monetary policy "leans against the wind" by raising real interest rates in response to expansionary shocks such as a government spending shock. Tax policy has at times also responded aggressively to government spending shocks (e.g., during the Korean war). The aggregate fiscal multiplier is potentially quite different in a setting in which monetary and tax policy are more accommodative, such as in the midst of a large recession. Since fiscal stimulus packages tend to be discussed exactly in such large recessions, evidence on the government spending multiplier for this circumstance is particularly valuable from a policy perspective.

Direct aggregate evidence on the effectiveness of government spending when monetary policy is constrained is, as one would expect, even less well established than on the simpler question of the average aggregate multiplier (see Ramey and Zubairy, 2017; Miyamoto et al., 2017). An indirect way to make inference about this question is, however, to amass evidence about whether a New Keynesian or Neoclassical model is a better description of the world. In the New Keynesian model, the aggregate multiplier is highly dependent on the responsiveness of monetary policy. If monetary policy is responsive, the aggregate multiplier can be quite low. But in circumstances when monetary policy is unresponsive—e.g., at the zero-lower-bound—the aggregate multiplier can be quite large. In contrast, in the Neoclassical model, the aggregate multiplier is small independent of monetary policy. Unfortunately, the evidence on the aggregate fiscal multiplier is not very helpful in this regard. In particular, estimates between 0.5 and 1.0—which is where most of the more credible estimates based on US data lie—are consistent with both of these models.

¹⁶The wealth effect associated with a fiscal shock should occur at the time of announcement. Theory suggests that an empirical approach that fails to capture this part of the effect of the fiscal shock will yield a response of output that is downward biased, but a response of consumption that is upward biased.

¹⁷Readers should be aware that it is standard in the fiscal VAR literature to report one standard error bands, presumably because two standard error bands are very wide.

3.2 Fiscal Stimulus: Cross-Sectional Evidence

Since the Great Recession, there has been an explosion of work that estimates the effects of government spending in the cross-section. Researchers in this literature have used a wide array of—in some cases very creative—identification strategies. Examples include windfall returns on state pension plans (Shoag, 2015), differential state sensitivity to military buildups (Nakamura and Steinsson, 2014), crackdowns on Mafia infiltrated municipalities in Italy (Acconcia et al., 2014), formulas used to allocate spending across states from the American Recovery and Reinvestment Act (Chodorow-Reich et al., 2012; Wilson, 2012; Dupor and Mehkari, 2016), and spending discontinuities associated with decadal population estimate revisions (Suarez Serrato and Wingender, 2016). Chodorow-Reich (2017) surveys this literature in detail.¹⁸

Estimates of the regional spending multiplier from this literature tend to cluster in the range of 1.5-2.0. They are therefore substantially larger than typical estimates of the aggregate multiplier. This does not, however, mean that these two sets of estimates are inconsistent. After all, they measure different things. To understand this better, let's consider the identification strategy we used in Nakamura and Steinsson (2014). The basic idea in our identification strategy is that national military buildups (e.g., the Carter-Reagan buildup following the Soviet invasion of Afghanistan in 1979) result in much larger changes in military spending in some states than others. This is because the plants that build the hardware used by the military are unevenly distributed across the country. For example, national military buildups imply that spending rises much more in California than in Illinois. We then ask whether this translates into bigger increases in output in California than in Illinois at these times.¹⁹ Our conclusion is that output in California rises by roughly \$1.5 relative to output in Illinois for each extra dollar of spending in California relative to Illinois.

Importantly, our specification includes time fixed effects implying that our multiplier estimates are only identified off of the response of California relative to Illinois, not the response of all states to the aggregate buildup. This also means that all aggregate general equilibrium effects are absorbed by the time fixed effects. These include any tightening of monetary policy that may occur as a consequence of the military buildup and the change in taxes needed to finance the buildup.

¹⁸The literature discussed above considered regional variation in government spending. Nekarda and Ramey (2011) consider variation in government spending across industries. They find that an increase in government demand raises output and hours worked, lowers real product wages and labor productivity, and has no effects on markups. They argue that their findings are more consistent with a neoclassical model than the textbook New Keynesian model.

¹⁹We regressed changes in regional output on changes in regional prime military contract spending controlling for region fixed effects and time fixed effects. We instrumented for changes in military spending using national prime military contract spending interacted with a region dummy.

Estimates of aggregate multipliers include these effects. Regional multiplier effects therefore do not provide direct evidence on the aggregate multiplier.

It turns out, however, that the regional multiplier is a powerful diagnostic tool for distinguishing between competing macroeconomic models, and thereby indirectly learning about the effectiveness of aggregate fiscal stimulus. In [Nakamura and Steinsson \(2014\)](#), we write down several multi-region business cycle models, simulate the same policy experiment in these models as we identify in the data (i.e., regional spending shocks financed with federal taxes), and compare the resulting regional multiplier estimates generated by each model with the regional multiplier estimate we estimate in real-world data. We find that both the textbook RBC model and the textbook New Keynesian model generate regional multipliers that are substantially smaller than our empirical estimate. The reason is that in these models a foreign demand shock (the federal government demanding military goods), leads people to cut back on work effort in other areas. The output response to such a shock is therefore less than one. We conclude that the regional multiplier evidence favors models in which output responds more strongly to a foreign demand shock than either the textbook RBC or New Keynesian models imply. We present an example of such a model and show that in this model the aggregate multiplier can be large (e.g., when monetary policy is constrained at the zero lower bound). The regional multiplier obviously does not point identify the correct model (no single statistic will). However, estimates of it should result in a posterior over models that puts less weight on a large class of models in which demand shocks have relatively small effects on output.

4 Monetary Policy: What Is the Best Evidence We Have?

What is the most convincing evidence we have for monetary non-neutrality? When we have asked prominent macroeconomists this question, the most common answers have been: [Friedman and Schwartz \(1963\)](#), the Volcker disinflation, and [Mussa \(1986\)](#).²⁰ [Friedman and Schwartz \(1963\)](#) famously argued that the severity of the Great Depression was due to bad policy by the Federal Reserve. They also point to a doubling of reserve requirements by the Federal Reserve between June 1936 and January 1937 and sterilization of gold inflows by the Treasury as a major cause for the sharp recession of 1937. Paul Volcker dramatically tightened monetary policy after taking office as chairman of the Federal Reserve Board in August 1979. These actions—which lasted

²⁰Of course, a significant fraction say something along the lines of “I know it in my bones that monetary policy has no effect on output.”

well into 1982 (with a brief easing in the spring of 1980)—are frequently cited as a major cause of the large twin recessions that occurred in 1980 and 1981-1982. Finally, international economists often point to the sharp break in the volatility of the US real exchange rate accompanying the breakdown of the Bretton Woods system of fixed exchange rates in 1973—first emphasized by [Mussa \(1986\)](#)—as dramatic evidence of monetary non-neutrality.

The fact that monetary economists point to these three pieces of evidence as most convincing is interesting and informative regarding the types of empirical methods that are influential in macroeconomics. Two of these three pieces of evidence are large historical events often cited without reference to modern econometric analysis: the Great Depression and the Volcker disinflation. The third is essentially an example of discontinuity-based identification. Conspicuous by its absence is any mention of evidence from Vector Autoregressions (VARs) even though such methods have dominated the empirical literature for quite some time. Clearly, there is a disconnect between what monetary economists find most convincing and what many of them do in their own research.

4.1 Large Shocks

The holy grail of empirical science is the controlled experiment. When it comes to monetary policy, for obvious reasons, we cannot do controlled experiments. We must instead search for “natural experiments”, i.e., situations in which we can argue that the change in policy is large relative to potential confounding factors that cannot be controlled for. Much empirical work takes the approach of seeking to control for confounding factors as well as possible. A different approach is to focus on large policy actions for which we can (hopefully) transparently argue that confounding factors are drowned out. Such policy actions are of course few and far between. But looking over a long period of history and many countries, one may be able to find events like these that constitute convincing pieces of evidence on the effects of monetary policy.

[Friedman and Schwartz \(1963, p. 688\)](#) argue in the summary of their monumental work on U.S. monetary history that three policy actions taken by the Federal Reserve in the interwar period were 1) “of major magnitude” and 2) “cannot be regarded as necessary or inevitable economic consequences of contemporary changes in money income and prices”. They furthermore argue that “like the crucial experiments of the physical scientist, the results are so consistent and sharp as to leave little doubt about their interpretation.” The dates of these events are January-June 1920, October 1931, and July 1936-January 1937. We will focus on the latter two of these events, which

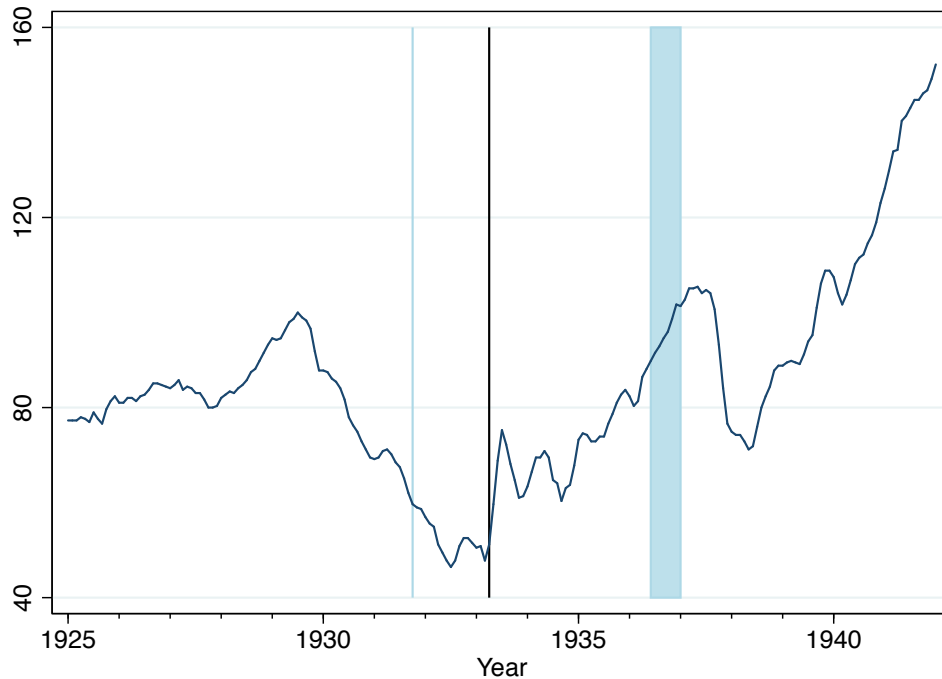

Figure 1: Industrial Production from 1925 to 1942

Note: The figure plots an index for industrial production in the US from January 1925 to January 1942. The index is equal to 100 in July 1929 (the peak month). The light blue shaded area and vertical line are the periods of policy mistakes identified by [Friedman and Schwartz \(1963\)](#). The black vertical line is the time at which Roosevelt took the US off the gold standard.

occurred during the Great Depression.

The Great Depression is by a wide margin the largest economic downturn in the United States in the last 150 years (if not ever). Figure 1 plots the evolution of industrial production from 1925 to 1942. Industrial production peaked in July of 1929. It then fell almost continuously until March 1933. The cumulative fall in industrial production was as staggering 53%. The recovery between March 1933 and the subsequent peak in May 1937 was rapid and large. Industrial production rose at an annual rate of 8.5% per year during that time to a level above the 1929 peak. But then a second very large downturn occurred. From May 1937 to May 1938 industrial production fell by 33%.

We have indicated with light blue vertical bars in Figure 1 the times of the two policy mistakes Friedman and Schwartz highlight. The first of these is October 1931. At this time, the Fed raised the rediscount rate sharply from 1.5% to 3.5% in response to a speculative attack on the US dollar that followed Britain's decision to leave the gold standard. The Fed drastically tightened policy at this time even despite the fact that industrial production was in free fall and a wave of bank

failures was underway. At first pass, this may seem like a very clean monetary shock. But the difficulty with it is that the subsequent fall in industrial production is not very different from the fall in the previous two years. It is not clear how much of the fall in industrial production between October 1931 and March 1933 is due to this policy shock as opposed to other developments that led to the the equally rapid fall in the two years before October 1931.

The second monetary shock emphasized by Friedman and Schwartz is more promising in this regard. During the period July 1936-January 1937 the Fed announced a doubling of reserve requirements (fully implemented by May 1937) and the Treasury engaged in sterilization of gold inflows. Before this period, industrial production had been rising rapidly. Shortly after, however, it plunged dramatically by 33%. Friedman and Schwartz argue that the increase in reserve requirements and sterilization of gold inflows caused a sharp slowdown in money creation, which caused the large 1937 recession. A closer look however reveals important confounding factors. Fiscal policy was tightened sharply in 1937.²¹ In fact, prior to Friedman and Schwartz's work, Keynesians often held up the 1937 recession as an example of the power of fiscal policy. [Romer and Romer \(1989\)](#) also emphasize that 1937 was a year of substantial labor unrest. For these reasons, it is perhaps not clear that this episode is "so consistent and sharp as to leave little doubt about [its] interpretation."

There is a more general argument that runs through Friedman and Schwartz's whole narrative of the Great Depression period. They argue that throughout the period between early 1930 and March 1933, the Fed failed to act and instead allowed the money supply to fall by large amounts and allowed a substantial fraction of the banking system to fail.²² [Eichengreen \(1992\)](#) argues that an important reason why the Fed did not act was that it felt constrained by the gold standard. The idea is that effective action almost surely would have been inconsistent with remaining on the gold standard and those that favored remaining on the gold standard prevailed until Roosevelt took office. One of President Roosevelt's first policy actions was to take the US off the gold standard in April 1933. The dollar quickly depreciated by 30%. The black vertical line in [Figure 1](#) indicates April 1933. Industrial production immediately sky-rocketed. The weakness of this observation is that the Roosevelt administration, of course, changed a number of policies. It seems clear that the switch from Hoover to Roosevelt mattered. Whether it was going off gold or something else that

²¹The budget balance swung substantially towards surplus because of the end of the 1936 veterans' bonus and the first widespread collection of social security payroll tax in 1937 among other factors.

²²They trace this failure to act to a power struggle within the Fed between the New York Fed that wanted to act and other parts of the Fed that favored inaction. They conclude that if Benjamin Strong—the powerful President of the New York Fed, who died in 1928—had lived the Fed might have ended the depression in 1930.

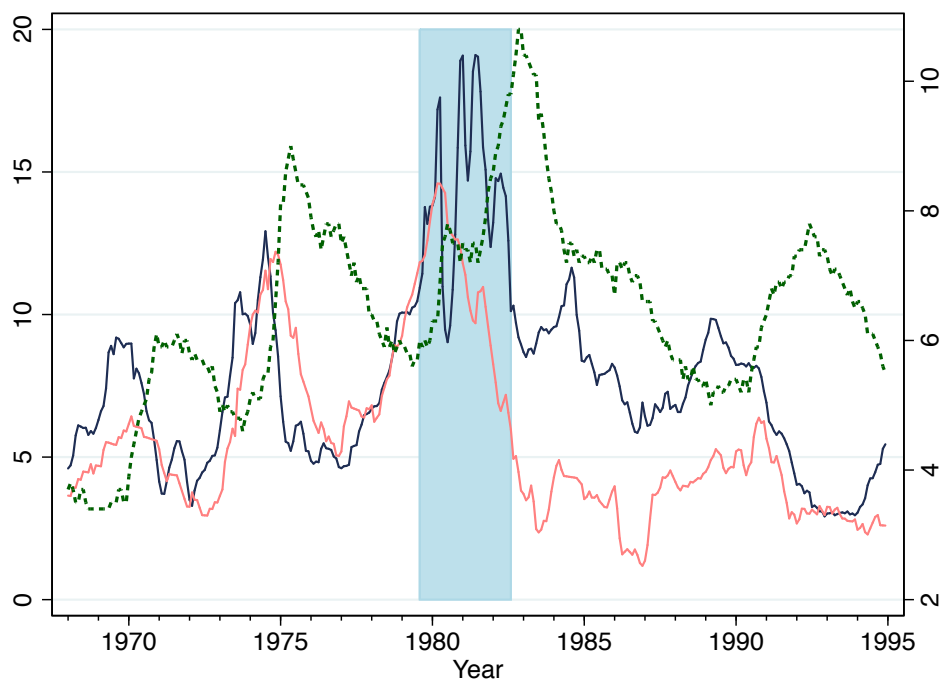

Figure 2: Federal Funds Rate, Inflation, and Unemployment from 1965 to 1995

Note: The figure plots the federal funds rate (solid blue, left axis), the 12-month inflation rate (solid pink, left axis), and the unemployment rate (dashed green, right axis). Volcker disinflation period shaded in blue (August 1979 to August 1982).

made the difference is, however, not entirely clear.²³

The Great Inflation of the late 1970's and early 1980's is another landmark event in US macroeconomic history. After having been low and stable since the end of the Korean War in 1953, inflation started to rise in the late 1960's. In the 1970's, inflation was both higher and much more volatile than before (see Figure 2). In 1974, President Ford declared inflation—then running at around 10% per year—“public enemy number one”. Inflation subsequently fell back to about 5% per year. But in 1978 and 1979 it rapidly rose back into double digits. Monetary policy during the 1970's is often described as “stop-go”—tight when the public was exercised about inflation and loose when the public was exercised about unemployment (Goodfriend, 2007).

In August 1979, Paul Volcker became the Chairman of the Federal Reserve Board, after having been appointed by President Carter. Under the leadership of Volcker, the Fed first conducted policy such that interest rates rose dramatically between October 1979 and March 1980. However,

²³A related piece of evidence that supports the case for going off gold as being crucial is that Eichengreen and Sachs (1985) show that countries that went off the gold standard earlier, recovered earlier from the Great Depression. Also, Eggertsson and Pugsley (2006) and Eggertsson (2008) present a model and narrative evidence suggesting that the turning points in 1933, 1937, and 1938 can all be explained by a commitment to reflate the price level (1933 and 1938) and an abandonment of that commitment (1937). Going off gold was an important element of this commitment in 1933.

the Fed then eased policy such that rates fell even more dramatically (by 9 percentage points) in the spring and summer of 1980 as it became clear that the economy was contracting strongly (see Figure 2). [Goodfriend and King \(2005\)](#) argue that this first year under Volcker was therefore not very different from earlier stop-go attempts by the Fed to reign in inflation. In the fall of 1980, inflation was no lower than a year earlier and the Fed’s credibility was if anything worse than before.

[Goodfriend and King \(2005\)](#) argue that it was only at this point—in November 1980—that Volcker truly broke with prior behavior of the Fed and embarked on a sustained, deliberate disinflation. He conducted policy such that rates rose dramatically to close to 20% and kept policy tight even in the face of the largest recession the US had experienced since the Great Depression. Only when inflation had fallen to 5% did Volcker let up and allow interest rates to drop substantially.

The behavior of output during this period is consistent with the view that monetary non-neutrality is large. Output fell dramatically in the spring and summer of 1980 shortly after the Fed raised interest rates sharply. Output then rebounded in late 1980 shortly after the Fed reduced interest rates sharply. Output then fell by a large amount for a sustained period in 1981-1982 while the Fed maintained high interest rates to bring down inflation. Finally, output started recovering when the Fed eased monetary policy in late 1982. Many economists find the narrative account above and the accompanying evidence about output to be compelling evidence of large monetary non-neutrality.²⁴ However, there are other possible explanations for these movements in output. There were oil shocks both in September 1979 and in February 1981 (see Table A.1 in the appendix). Credit controls were instituted between March and July of 1980. It may even be that anticipation effects associated with the phased-in tax cuts of the Reagan administration played a role in the 1981-1982 recession ([Mertens and Ravn, 2012](#)).

While the Volcker episode is consistent with a large amount of monetary non-neutrality, it seems much less consistent with the commonly held view that monetary policy affects output with “long and variable lags.” To the contrary, what makes the Volcker episode compelling is that output fell and then rose and then fell again largely in sync with the actions of the Fed. If not for this, it would have been much harder to attribute the movements in output to changes in policy.

²⁴The Volcker disinflation has also had a profound effect on beliefs within academia and in policy circles about the ability of central banks to control inflation. The idea that inflation is “always and everywhere a monetary phenomenon” was a proposition that (surprisingly to modern ears) was doubted by many in the 1970’s ([Romer and Romer, 2002](#); [Nelson, 2005](#)). Estimates of the “sacrifice ratio” associated with bringing down inflation—i.e., the cost in terms of output of a permanent 1 percentage point reduction in inflation—were huge in the late 1970’s ([Okun, 1978](#)). Also, the idea that credible announcements to disinflate can reduce these costs was not well understood or widely believed.

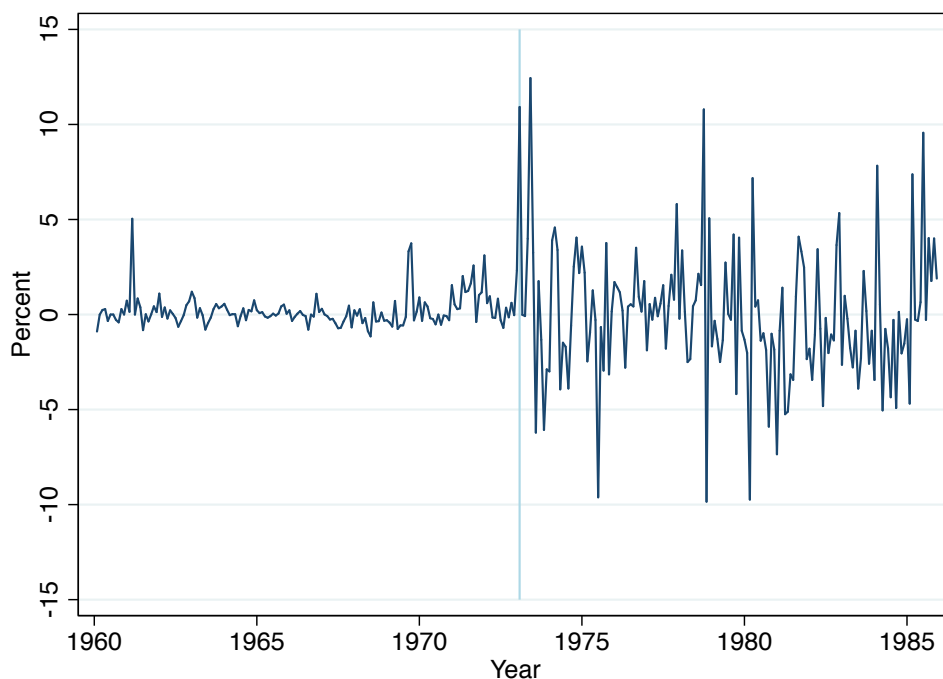

Figure 3: Monthly Change in the US-German Real Exchange Rate

4.2 Discontinuity-Based Identification

There is incontrovertible, reduced-form evidence that monetary policy affects relative prices. The evidence on this point is strong because it can be assessed using discontinuity-based identification methods. The pioneering paper on this topic is [Mussa \(1986\)](#). He argued that the abrupt change in monetary policy associated with the breakdown of the Bretton Woods system of fixed exchange rates in February 1973 caused a large increase in the volatility of the US real exchange rate.²⁵ Figure 3 plots the monthly change in the US-German real exchange rate from 1960 to 1990. There is a clear break in the series in February 1973: its standard deviation rose by more than a factor of four (comparing two year periods before and after). The switch from a fixed exchange rate to a flexible exchange rate is a purely monetary action. In a world in which monetary policy has no real effects, such a policy change will not affect real variables such as the real exchange rate. Figure 3 demonstrates dramatically that the world we live in is not such a world.

As with any discontinuity-based identification scheme, the identifying assumption being made

²⁵The Bretton Woods system officially broke down on March 1st 1973. However, we date the de facto breakdown as February 1973 because the exchange rate of the dollar vis-a-vis major European countries and Japan was allowed to move substantially in that month in response to mounting pressure. For example, on February 12th 1973 the US devalued the dollar by 10%. See [Bordo, Humpage, and Schwartz \(2011\)](#) for a detailed discussion of the breakdown of the Bretton Woods system.

is that other factors affecting the real exchange rate do not change *discontinuously* in February 1973. The breakdown of the Bretton Woods system was caused by a gradual build-up of imbalances over several years. The root cause was persistently more inflationary macroeconomic policy in the United States than in Germany, Japan, and other countries. By early 1973, the US exchange rate was overvalued and the US had a substantial current account deficit, while Germany and other countries had substantial surpluses. There were intense negotiations about the future of the system for over a year before it finally collapsed. It is hard to think of plausible alternative candidate explanations for the *discontinuous* increase in the volatility of the US real exchange rate that occurred at this time.²⁶

There is also strong evidence that monetary policy affects real interest rates. This can be established at very high frequencies using the response of the yields on Treasury Inflation Protected Securities (TIPS)—which provide a measure of relatively risk-free real interest rates—to monetary announcements. Importantly, a large amount of monetary news is revealed discretely at the time of the eight regularly scheduled meetings of the Federal Open Market Committee (FOMC) of the Federal Reserve. This allows for a discontinuity-based identification scheme.

In Nakamura and Steinsson (2017), we construct monetary shocks using changes in interest rates over a 30-minute window surrounding FOMC announcements. Over such a short window, movements in interest rates are dominated by the monetary announcement.²⁷ Furthermore, any systematic response of the Fed to information about the economy that is public at the time of the announcement is already incorporated into financial markets, and, therefore, does not show up as spurious variation in the monetary shocks we construct. We show that nominal and real interest rates respond roughly one-for-one to these monetary shocks several years out into the term structure of interest rates, while expected inflation responds little. For example, the 3-year nominal and real forward rates respond by very similar amounts. Hanson and Stein (2015) present similar empirical results.

Direct high frequency evidence of the effect of monetary policy on *output* is much weaker than for relative prices (Cochrane and Piazzesi, 2002; Angrist, Jorda, and Kuersteiner, 2017). The reason for this is that high-frequency monetary shocks are quite small—as is often the case with very

²⁶Velde (2009) presents high-frequency evidence on the effects of a large monetary contraction in 18th century France. He shows that domestic prices responded sluggishly and incompletely to this shock. He also presents evidence on output. As with more modern evidence, Velde’s evidence on output is less conclusive. Burstein et al. (2005) show that large, abrupt devaluations lead to large changes in real exchange rates that are mostly due to changes in the relative price of non-tradable goods.

²⁷We verify this using a heteroskedasticity-based identification scheme building on the work of Rigobon (2003) and Rigobon and Sack (2004).

clearly identified shocks. This implies that the statistical power to assess their effect on output several quarters in the future is limited (since many other shocks affect output over such a long time period). However, the effect of monetary shocks on output can be broken into two separate questions: 1) How much do monetary shocks affect various relative prices? and 2) How much do these various relative prices affect output? Viewing things this way makes clear that it is the first of these two questions that is *the* distinguishing feature of models in which monetary policy has effects on output. All models—Neoclassical and New Keynesian—imply that relative prices affect output. Only in some models does monetary policy affect relative prices, and these models typically imply that money is non-neutral. The use of discontinuity-based evidence regarding the effect of monetary shocks on relative prices to make inference about monetary non-neutrality is therefore a good example of the identified moment matching approach we discuss earlier in this article.

A complicating factor regarding the high-frequency evidence from FOMC announcements discussed above is that these announcements may lead the private sector to update its beliefs not only about the future path of monetary policy, but also about other economic fundamentals. If the Fed Chair reveals that (s)he is more optimistic about the economy than the private sector had anticipated, this may lead the private sector to revise its own beliefs about where the economy is headed. In fact, we find evidence for such “Fed information effects” in [Nakamura and Steinsson \(2017\)](#). A surprise tightening of policy is associated with an *increase* in expected output growth in the Blue Chip survey of professional forecasters (the opposite of what standard analysis of monetary shocks would imply).²⁸ We show that a New Keynesian model that incorporates Fed information effects can match this fact as well as the facts about real interest rates and expected inflation. In this model, Fed tightenings have two effects on the economy: traditional contractionary effects through increases in real interest rates relative to natural rates and a less traditional expansionary effects coming from the Fed’s ability to increase optimism about the economy.

The existence of this Fed information effect implies that there is an “external validity” problem whenever researchers try to use responses to monetary shocks to make inference about the effects of systematic monetary policy actions. Surprise monetary actions lead to information effects. Changes in policy that are expected because they are part of the systematic response of the Fed to developments in the economy do not lead to information effects. This implies that the responses to monetary shocks estimated in the literature likely underestimate the effect of systematic monetary

²⁸See [Romer and Romer \(2000\)](#), [Faust, Swanson, and Wright \(2004\)](#), and [Campbell et al. \(2012\)](#) for earlier evidence of Fed information effects.

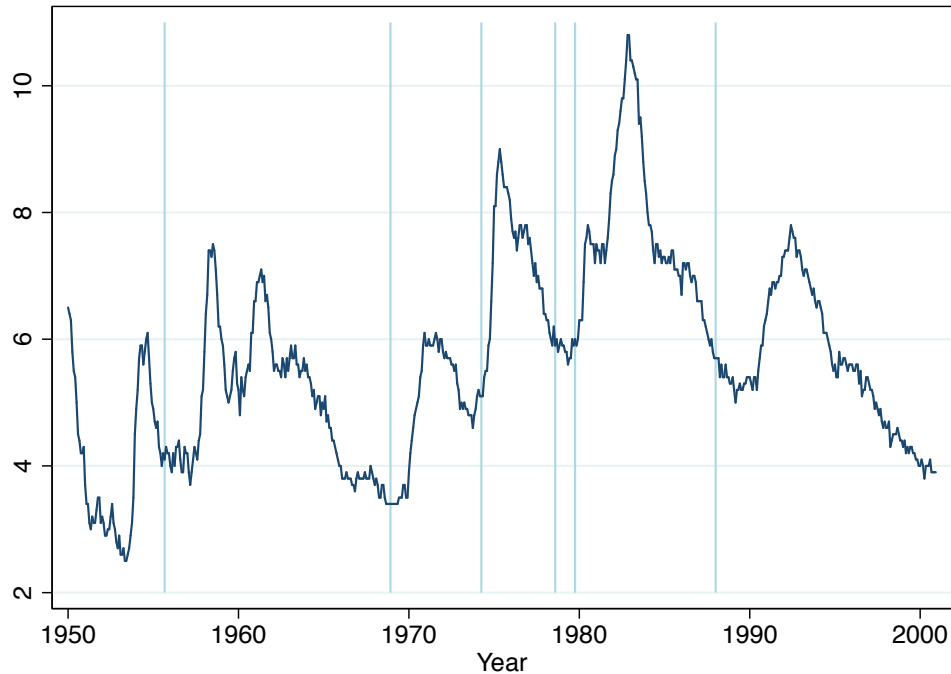

Figure 4: Unemployment from 1950 to 2000

Note: The figure plots the unemployment rate from 1950 to 2000. The light-blue vertical lines indicate Romer-Romer dates.

policy (but less so in periods when information effects were less likely to be important).

4.3 Using the Narrative Record to Identify Shocks

Identification involves the search for natural experiments. [Romer and Romer \(1989\)](#) argue that contemporaneous Federal Reserve records can be used to identify such natural experiments. Specifically, they use such records to identify “episodes in which the Federal Reserve attempted to exert a contractionary influence on the economy in order to reduce inflation” in the post-WWII period. They identify six such times and have subsequently added a seventh ([Romer and Romer, 1994](#)). [Figure 4](#) plots the US unemployment rate with the seven Romer-Romer dates marked by vertical lines. After each of the Romer-Romer dates, unemployment rises sharply. Pooling the data from these seven episodes, Romer and Romer argue that together they constitute strong evidence for substantial real effects of monetary policy.

While this “narrative approach” to identification is clearly very valuable, it faces several challenges. First, narrative shocks are selected by an inherently opaque process. This raises the concern that the results are difficult to replicate. An advantage of simple, transparent, empirical

strategies is that it is easier for readers to evaluate the key assumptions that yield identification.

Second, with only seven data points, it may happen by chance that some other factor is correlated with the monetary shocks. In cases when one has dozens or hundreds of shocks that are plausibly orthogonal to other factors, any random correlation with some other factor is likely to average to zero. But with seven data points, this may not happen. In fact, Hoover and Perez (1994) argue that Romer and Romer's monetary dates are strikingly temporally correlated with dates of oil shocks (see Table A.1 in the appendix).

Third, narrative shocks are often found to be predictable suggesting endogeneity. In the case of Romer and Romer's (1989) analysis, this type of concern was raised by Citeshapiro1994 and Leeper (1997). However, it is difficult to convincingly establish predictability due to overfitting concerns. The cumulative number of regressions run by researchers trying to assess the predictability of narrative shocks may be very large. Even by chance, some of these should turn up estimates that are statistically significant based on standard significance cutoffs.²⁹

4.4 Controlling for Confounding Factors

By far, the most prevalent approach to identifying exogenous variation in monetary policy is to attempt to control for confounding factors. This is the approach taken in much of the VAR literature. A common specification is to regress the federal funds rate on contemporaneous values of several variables (output, inflation, etc.), as well as several lags of itself and these other variables and to view the residual from this regression as exogenous monetary policy shocks. A common way of describing this procedure is as performing a Cholesky decomposition of the reduced form errors from the VAR with the federal funds rate ordered last.

This approach to identifying monetary policy shocks is often described as involving "minimal identifying assumptions." In our view, however, these are very strong assumptions. What is being assumed is that controlling for a few lags of a few variables captures all endogenous variation in policy. This seems highly unlikely to be true in practice. The Fed bases its policy decisions on a huge amount of data. Different considerations—in some cases highly idiosyncratic—affect policy at different times. Stress in the banking system affects policy in some periods. In other periods, sharp changes in commodity prices affect policy. In yet other periods, a recent stock market crash affects policy, or a financial crisis in emerging markets, or terrorist attacks, or temporary invest-

²⁹In the case of Leeper's results, Romer and Romer (1997) present a simple pseudo-out-of-sample procedure demonstrating dramatic overfitting. They redo Leeper's analysis seven times, in each case leaving out one of the monetary shock dates. For each set of estimates, they then see if the model can predict the shock date that is left out. Using this pseudo-out-of-sample procedure, they find no predictability.

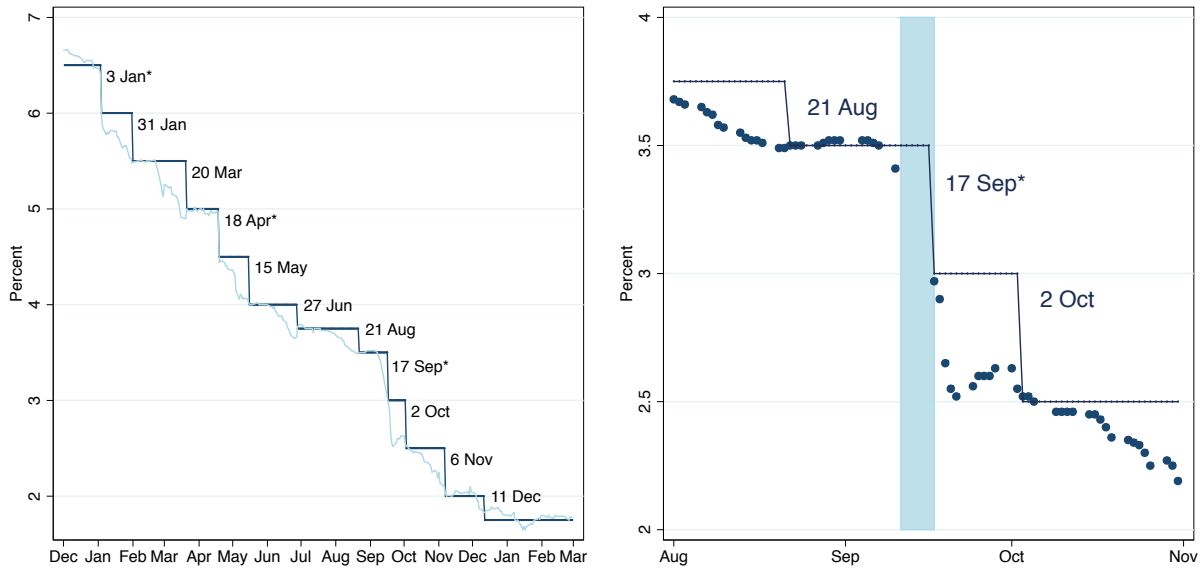

Figure 5: Federal Funds Rate Target and 1-Month Eurodollar Rate

Note: The figure plots the federal funds rate target (blue line) and the 1-month Eurodollar rate (red line in left panel and blue dots in right) at a daily frequency (beginning of day). Dates of changes in the federal funds rate target are indicated in the figure. The dates marked with a * are unscheduled FOMC conference calls. The other dates are scheduled FOMC meetings. The left panel is very similar to the top panel of Figure 1 in [Cochrane and Piazzesi \(2002\)](#).

ment tax credits, or the Y2K computer glitch. The list goes on and on. Each of these considerations may only affect policy in a meaningful way on a small number of dates and the number of such influences is so large that it is not feasible to include them all in a regression without risking massive over-fitting concerns or literally run out of degrees of freedom. Any one of these factors that is left out will result in a monetary policy “shock” that the researcher views as exogenous but is in fact endogenous. [Rudebusch \(1998\)](#) is a classic discussion of these concerns.

To concretely demonstrate this point, it is useful to consider an example. Following [Cochrane and Piazzesi \(2002\)](#), Figure 5 plots the evolution of the federal funds rate target of the Federal Reserve as well as the 1-month Eurodollar rate—i.e., a 1-month interbank interest rate on US dollars traded in London—over the period December 2000 to February 2002. The Eurodollar rate on any given day may be viewed as the average expected federal funds rate over the next month. On September 10th 2001, the Eurodollar rate traded at 3.41%, quite close to the target federal funds rate of 3.5%. Markets did not open on September 11th 2001 due to the terrorist attacks in New York and stayed closed until Monday September 17th 2001. Before markets opened on that day, the Fed announced a 50bp drop in the target federal funds rate to 3% and the 1-month Eurodollar rate traded at 2.97% that day. The futures contract for the federal funds rate in September 2001

reveals that this 50bp drop in the federal funds rate was completely unanticipated by markets as of September 10th.³⁰ The easing on September 17th was obviously due to the terrorist attacks and therefore obviously endogenous: the terrorist attacks caused the Fed to revise its assessment about future growth and inflation leading to an immediate drop in interest rates.

How do standard monetary VARs treat 9/11? As an exogenous monetary shock. The reason is that the controls in the policy equation of the VAR are not able to capture the changes in beliefs that occur on 9/11. Nothing has yet happened to any of the controls in the policy equation (even in the case of a monthly VAR). From the perspective of this equation, therefore, the drop in interest rates in September 2001 looks like an exogenous easing of policy.³¹ Any unusual (from the perspective of the VAR) weakness in output growth in the months following 9/11 will then, perversely, be attributed to the exogenous easing of policy at that time. Clearly, this is highly problematic.

The way in which identification assumptions are commonly discussed in the VAR literature is very misleading, in our view. It is common to see “the” identifying assumption in a monetary VAR described as the assumption that the federal funds rate does not affect output and inflation contemporaneously (or, in the fiscal multiplier case, that government spending is not affected by contemporaneous changes in output). These assumptions sound quite innocuous. To an outsider, the whole thing sounds like magic: You make one pretty innocuous assumption, and voilà, you can estimate the dynamic causal effects of monetary and fiscal policy. We remember finding this deeply puzzling when we were starting off in the profession.

In fact, the timing assumption that is usually emphasized is not the only identifying assumption being made in a standard monetary or fiscal VAR. The timing assumption rules out reverse causality: Output and interest rates are jointly determined. An assumption must be made about whether the contemporaneous correlation between these variables reflects a causal influence of one on the other or the reverse. This is what the timing assumption does.

But reverse causality is not the only issue when it comes to identifying exogenous variation in policy. Arguably, a much bigger issue is whether monetary policy is reacting to some other piece of information about the current or expected future state of the economy that is not included in the VAR, i.e., omitted variables bias. The typical VAR includes a small number of variables and a small number of lags (usually one year worth of lagged values). Any variable not sufficiently well

³⁰The 1-month Eurodollar rate was trading below the target for the federal funds rate on September 10th because markets were anticipating an easing of 25-50bp at the regularly scheduled FOMC meeting on October 2nd. When markets opened on September 17th, markets anticipated an easing of an additional 25-50bp on October 2nd (over and above the 50bp that had just occurred).

³¹We have verified this. The monthly VAR used by [Coibion \(2012\)](#) yields a monetary shock of -48bp in September 2001.

proxied by these variables is an omitted variable. The omission of these variables leads endogenous variation in policy to be considered exogenous.³²

The extremely rich nature of the Fed's information set means that it is arguably hopeless to control individually for each relevant variable. [Romer and Romer \(2004\)](#) propose an interesting alternative approach. Their idea is to control for the Fed's own forecasts (the so called Greenbook forecasts). The logic for this idea is that the endogeneity of monetary policy is due to one thing and one thing only: what the Fed thinks will happen to the economy. If one is able to control for this, any residual variation in policy is exogenous. For this reason, the Fed's forecasts are a sufficient statistic for everything that needs to be controlled for. It is useful to be concrete. Suppose we are interested in the effect of a change in monetary policy at time t , denoted Δr_t , on the change in output over the next j months, $\Delta^j y_{t+j} = y_{t+j} - y_{t-1}$. The potential concern is that Δr_t may be correlated with some other factor that affects $\Delta^j y_{t+j}$. But this can only be the case if the Fed knows about this other factor, and to the extent that it does, this should be reflected in the Fed's time t forecast of $\Delta^j y_{t+j}$. Controlling for the Fed's time t forecast of $\Delta^j y_{t+j}$ should therefore eliminate all variation in policy that is endogenous to the determination of $\Delta^j y_{t+j}$.³³

Romer and Romer's approach helps answer the question: What is a monetary shock? As [Cochrane \(2004\)](#) notes, the Fed does not roll dice. Every movement in the intended federal funds rate is in response to something. Some are in response to developments that directly affect $\Delta^j y_{t+j}$. These are endogenous, when $\Delta^j y_{t+j}$ is the dependent variable. But others are in response to other things. Examples include time variation in policy makers' preferences and goals (e.g., distaste for inflation), time variation in policy makers' beliefs about how the economy works, political influences, pursuit of other objectives (e.g., exchange rate stability), etc.³⁴ Importantly, changes in policy need *not* be unforecastable as long as they are orthogonal to the Fed's forecast of the dependent variable in question.³⁵

³²In the econometrics literature on structural VARs, this omitted variables issue is referred to as the non-invertibility problem. An impulse response to a particular shock is said to be invertible if the shock can be recovered as a linear function of current and past values of the observable data. The existence of omitted variables therefore implies non-invertibility. See [Hansen and Sargent \(1991\)](#), [Fernandez-Villaverde et al. \(2007\)](#), and [Plagborg-Møller \(2017\)](#).

³³This discussion is based on [Cochrane \(2004\)](#).

³⁴The main threat to validity for this approach is that some variable affects both Δr_t and $\Delta^j y_{t+j}$ conditional on the Greenbook forecast. If the Greenbook forecast at time t is an efficient forecast of $\Delta^j y_{t+j}$, no such variable can exist (since no variable forecasts $\Delta^j y_{t+j}$ conditional on the Fed's forecast, in that case). If the Fed's forecast is inefficient, such a variable may exist. However, for the variable to be a problem, it must influence both Δr_t and $\Delta^j y_{t+j}$ conditional on the Greenbook forecast.

³⁵Changes in policy that are forecastable (e.g., forward guidance) are more complicated to analyze since they can have effects both upon announcement and when they are implemented.

4.4.1 What Do We Do with These Shocks?

Any exercise in dynamic causal inference involves two conceptually distinct steps: 1) the construction of the shocks, 2) the specification used to construct an impulse response once one has the shocks in hand. We have discussed the first of these steps in detail above. But the second step is also potentially very important. A specification that imposes minimal structure (apart from linearity) is to directly regress the variable of interest ($\Delta^j y_{t+j}$, say) on the shock, perhaps controlling for some pre-treatment variables (i.e., variables determined before date t). This is the specification advocated by [Jorda \(2005\)](#). To construct an impulse response using this approach, one must run a separate regression for each horizon j that one is interested in plotting.

Standard VARs construct impulse response functions using a very different approach that imposes much more structure: they use the estimated dynamics of the entire VAR system to iterate forward the response of the economy to the shock. This method for constructing impulse responses embeds a whole new set of quite strong identifying assumptions. In a standard monetary VAR, whether the shocks truly represent exogenous variation in monetary policy only relies on the regression equation for the policy instrument being correctly specified. In contrast, the construction of the impulse response relies on the entire system of equations being a correct representation of the dynamics of all the variables in the system, i.e., the whole model being correctly specified.

It is well known that the solution to any linear rational expectations model can be represented by a VAR. This idea is the usual defense given regarding the reasonableness of VAR impulse response construction. However, to estimate the true VAR, all state variables in the economy must be observable (so that they can be included in the VAR). If this is not the case, the VAR is misspecified and the impulse responses that it yields are potentially biased. Suppose one of the state variables in the system is not observable. One strategy is to iteratively solve out for that variable. The problem with this is that it typically transforms a VAR(p) system into a VARMA(∞, ∞) system in the remaining variables. The estimation of VARs therefore relies on the assumption that the true VARMA(∞, ∞) in the variables the researcher intends to include in his/her analysis can be approximated with a VAR(p). This is a strong assumption that we fear is unlikely to hold in practice.³⁶

³⁶Problem set for interested readers: Consider the following simple New Keynesian model. Phillips curve: $\pi_t = \beta E_t \pi_{t+1} + \kappa(y_t - y_t^n)$. Aggregate demand equation: $\Delta M_t = \Delta y_t + \pi_t$. Monetary shock: $\Delta M_t = \rho \Delta M_{t-1} + \epsilon_t$. Productivity shock: $y_t^n = \eta_t$. Assume ϵ_t and η_t are i.i.d. normal. Set the parameters to $\beta = 0.99$, $\kappa = 0.13$, $\rho = 0.8$, $\sigma_\epsilon = 0.00066$, $\sigma_\eta = 0.007$ (the last two are chosen so that the contribution of ΔM_t and y_t^n to the variance of y_t is equal). 1) Show that the solution for output in this model takes the form $y_t = ay_{t-1} + b\Delta M_{t-1} + c\epsilon_t + d\eta_t$ (hint: method of undetermined coefficients). 2) Calculate the true impulse response of output to a monetary shock. 3) Simulate 500 time series from the model each of length 500 data points. Estimate the following three misspecified empirical models for

A recent innovation in dynamic causal inference is the use of “external instruments” in VARs (Stock and Watson, 2012; Mertens and Ravn, 2013; Stock and Watson, 2017). Gertler and Karadi (2015) use this method to estimate the effects of exogenous monetary shocks on output, inflation, and credit spreads. Their measure of exogenous variation in monetary policy is the surprise movement in the 3-month-ahead fed funds rate futures contract in a 30-minute window around FOMC announcements. They then run a monthly VAR and instead of viewing the reduced form error in the interest rate equation as the monetary shock, they regress all the reduced form residuals on their “external” monetary policy shock. This yields a vector of contemporaneous responses of the variables in the VAR to the monetary shock (non of which is constrained to be zero). Finally, they construct an impulse response by iterating forward the VAR dynamics starting with this contemporaneous response. Figure 6 reproduces Figure 1 from Gertler and Karadi (2015). The column on the left gives impulse responses using external instruments, while the column on the right uses a standard Cholesky decomposition (see the figure note for details).

An important advantage of the external instruments approach relative to standard monetary VARs that rely on a Cholesky ordering is that it is possible to include fast-moving financial variables—such as stock prices, exchange rates, and credit spreads—in the VAR. In a standard monetary VAR, one must make a stark choice regarding the direction of contemporaneous causation of each variable with the policy variable: either it runs only from the policy variable to the variable in question or it runs only the other way. This is clearly unsatisfactory for variables such as stock prices, exchange rates, and credit spreads. The notion that the contemporaneous values of stock prices, exchange rates, and credit spreads do not contain useful information about the endogenous component of monetary policy (even conditional on the other variables in the VAR) is highly dubious. This would suggest including them in the policy equation so as to get a cleaner measure of exogenous policy actions. However, if this is done, one cannot use the VAR dynamics to iterate forward the impulse response without assuming that these variables do not react to exogenous policy actions contemporaneously, which is inconsistent with much evidence (see, e.g., Gurkaynak, Sack, and Swanson, 2005; Bernanke and Kuttner, 2005, for stock prices).

However, while VARs identified with external instruments relax the Cholesky timing assump-

output for each of these series: a model with the contemporaneous monetary shock and one lag of output, a model with the contemporaneous monetary shock and four lag of output, a model with the contemporaneous monetary shock and twelve lag of output. Plot the median impulse response for each misspecified empirical model. Notice that adding 12 lags of output doesn’t help at all in matching the true impulse response even though the true impulse response “looks like” an AR(2). 4) Do the same for a model with one lag of output, the contemporaneous monetary shock, and 6 lags of the monetary shock. Notice that this matches the true impulse response out to horizon 6 (but is biased after that). 5) Finally, do the same using the Jorda specification (with or without controls). Notice that this matches the true impulse response almost perfectly.

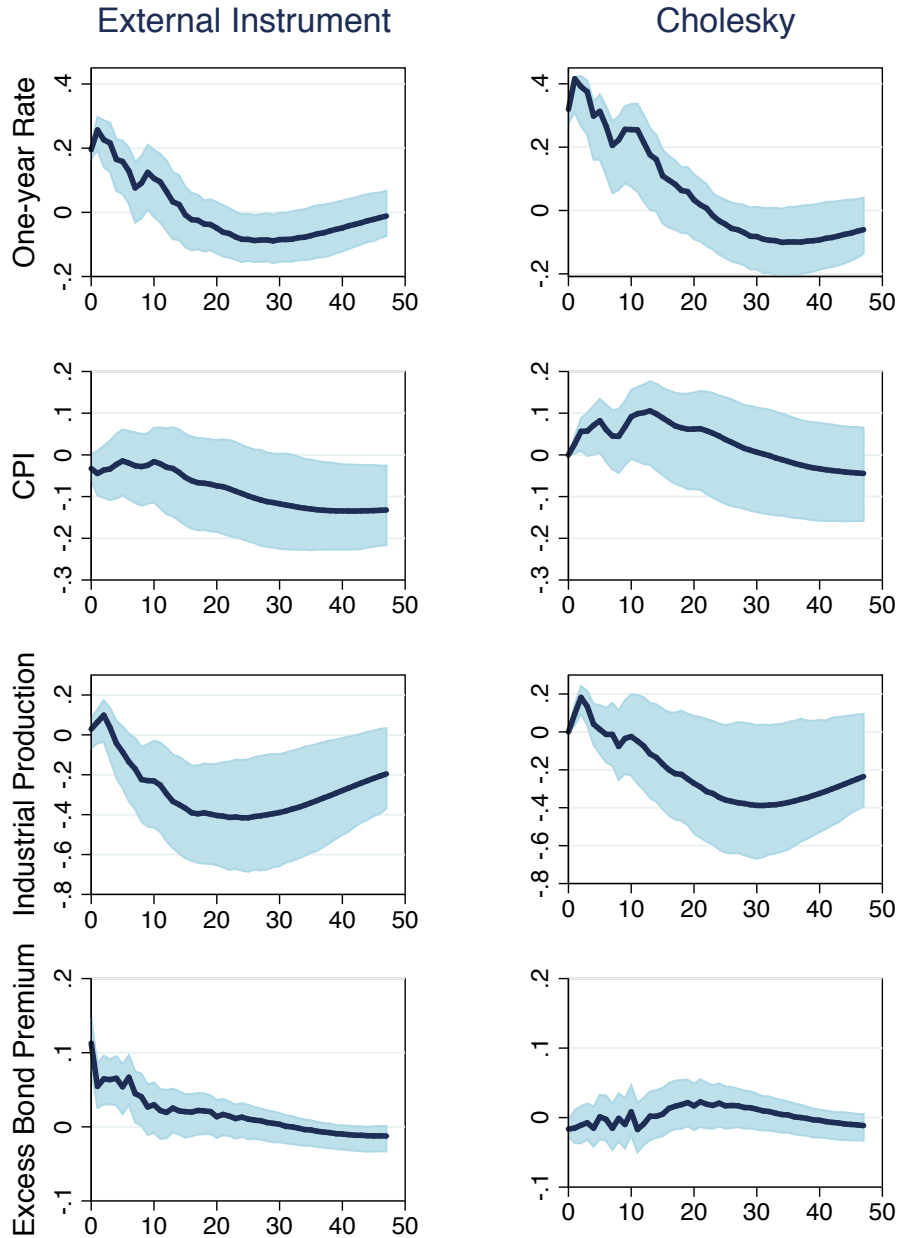

Figure 6: Responses to Monetary Shocks from [Gertler and Karadi \(2015\)](#)

Note: This figure replicates Figure 1 in [Gertler and Karadi \(2015\)](#). The figure plots the response of the one-year Treasury bond yield, the CPI, industrial production, and a measure of the excess bond premium in response to monetary policy shocks identified in two different ways. The left column uses external instruments to identify the contemporaneous response to the monetary shocks. The right column uses a Cholesky decomposition with the one-year yield considered the policy instrument and this variable ordered second to last with the excess bond premium ordered last. In both cases, the responses after the initial period are calculated by iterating forward a VAR with these four variables.

tions for contemporaneous responses, they do not relax the assumptions embedded in using the VAR system to construct the impulse response. This methodology still must assume that the VAR is a correct representation of the dynamics of all the variables in the system (the model is correct). Consider the response of industrial production in Figure 6. The external instruments approach allows the contemporaneous response of industrial production to be non-zero. In fact, however, it is estimated to be very close to zero (i.e., not very different from the Cholesky case). The fact that the response of industrial production is different at later horizons is therefore mainly due to dynamic influences of other variables on industrial production as estimated in the VAR (most notably differences in the response of the excess bond premium and its estimated effect on output in the VAR). In other words, while the contemporaneous responses are estimated more freely, the VAR dynamics are still doing a lot of the work when it comes to the inference about responses at future horizons.³⁷

4.4.2 An Example: Romer and Romer Versus VARs

We have discussed different ways to identify monetary shocks and different ways to construct impulse responses using these shocks. We close this section with an example where we contrast these different methods in a setting in which they yield quite different results. Coibion (2012) has drawn attention to the fact that Romer and Romer's (2004) results about the impact of monetary shocks contrast sharply with those of standard monetary VARs. The peak responses of industrial production and unemployment to a change in the federal funds rate are roughly six times larger in Romer and Romer (2004) than in a standard monetary VAR. Furthermore, while the contribution of monetary policy shocks to fluctuations in unemployment and inflation is quite modest according to a standard monetary VAR, monetary policy shocks account for a very large portion of fluctuations in these variables according to Romer and Romer's results.

Figure 7 presents six different estimates of the response of industrial production and the real interest rate to monetary shocks. The two columns present results based on different monetary shocks: results in the left column are based on monetary shocks from a standard monetary VAR (the VAR used in Coibion (2012)), while results in the right column are based on Romer and Romer's (2004) monetary shocks.³⁸ In the three rows, different methods are used to construct

³⁷The use of sign restrictions is another recent development in this area (see, e.g., Uhlig, 2017).

³⁸Coibion's (2012) VAR is a monthly VAR that includes the logarithm of industrial production, the unemployment rate, the logarithm of CPI, the logarithm of a commodity price index, and the effective federal funds rate, in that order. Twelve lags are included. Standard errors are constructed using a wild bootstrap (Goncalves and Kilian, 2004; Mertens and Ravn, 2013). For Romer and Romer's (2004) shocks, we use a version of compiled by Wieland and Yang (2017).

impulse responses: in the top row impulse responses are constructed using VAR dynamics, in the middle row using the Jorda specification, and in the bottom row using the single-equation method employed by [Romer and Romer \(2004\)](#).³⁹ The sample period is 1970-1996—the same sample period as in [Romer and Romer \(2004\)](#).⁴⁰

There are two things we would like to emphasize about the results presented in [Figure 7](#). First, both the shocks used and the method used to construct impulse responses matters a great deal for the conclusions reached. The Romer-Romer shocks generate much larger effects than the VAR shocks. The VAR impulse responses suggest that the standard errors are substantially smaller than the other methods for constructing impulse responses. Finally, the Romer-Romer method for constructing impulse response generated much larger effects than the other two. Clearly, it matters a great deal which methods are used both for constructing shocks and estimating impulse responses.

The second important lesson illustrated by [Figure 7](#) has to do with how to best measure the size of the response. The direct comparison between [Romer and Romer's \(2004\)](#) results and those from a standard monetary VAR can be seen by comparing the top-left panel (VAR) with the bottom-right panel (Romer-Romer). The response of industrial production is clearly much bigger for Romer-Romer than VAR. But notice that the response of the real interest rate is also much bigger. Loosely speaking, this means that the “treatment” in the Romer-Romer panel is much bigger. It stands to reason that this contributes substantially to the bigger response of industrial production in the Romer-Romer panel.

To get a meaningful measure of the effect of a treatment, one must divide the size of the response with the size of the treatment in each case. One way to do this is to sum up the response of industrial production over some time horizon, sum up the response of the real interest rate over the same horizon, and divide the cumulative response of one by the other. This is what is done in [Table 1](#) using a horizon of 36 months. While the peak response of industrial production is roughly 6 times larger in Romer-Romer than VAR, the cumulative response of industrial production scaled by the cumulative response of real interest rates is only 2.5 times larger (3.5 versus 1.4). This illus-

³⁹Romer and Romer regress industrial production on 36 lags of their monetary shocks as well as 24 lags of industrial production and month dummies. They then construct an impulse response function by iterating forward the response of industrial production to a shock (including the effects of the lagged dependent variables). In the Jorda specification, we include two lags of the five variables in Coibion's VAR as controls. The standard errors in the top row are constructed using a wild bootstrap ([Goncalves and Kilian, 2004](#); [Mertens and Ravn, 2013](#)). In the middle panel, we use [Newey and West \(1987\)](#) standard errors with a lag length equal to 1 plus the horizon in question. The standard errors in the bottom two panels are constructed based on estimates of the asymptotic distribution of the parameters as in [Romer and Romer \(2004\)](#).

⁴⁰See [Figure A.1](#) in the appendix for an analogous figure plotting the response of the CPI and the nominal interest rate.

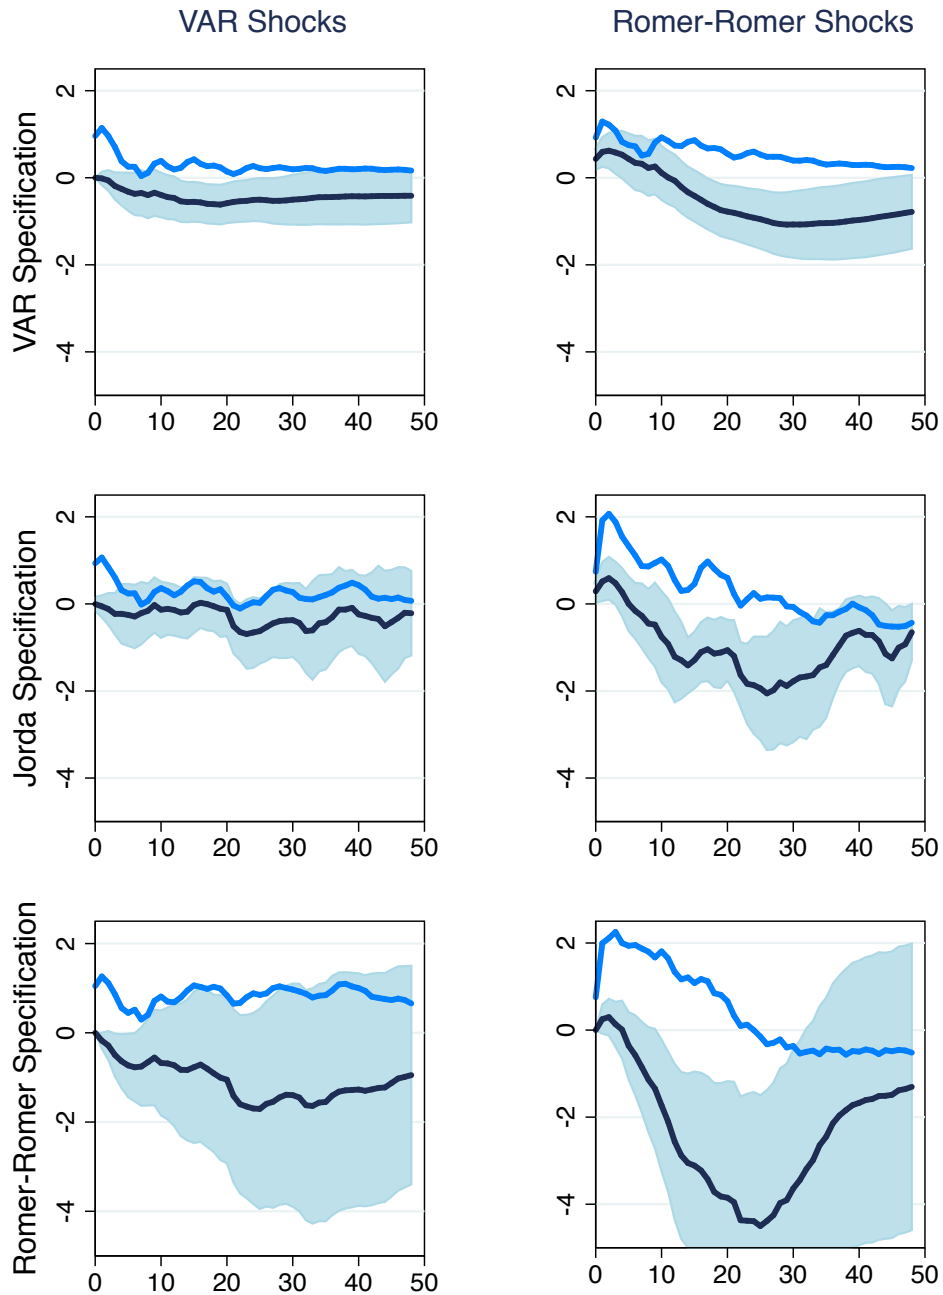

Figure 7: Response of Industrial Production and the Real Interest Rate to Monetary Shocks

Note: The figure plots the response of industrial production (black line) and the real interest rate (blue line) to monetary shocks calculated in six different ways. The light-blue area represents a 95% confidence band for industrial production. The three panels on the left use the monetary shocks produced by Coibion's (2012) monthly VAR, while the three panels on the right use Romer and Romer's (2004) monetary shocks. The top two panels use Coibion's (2012) VAR specification to construct the impulse response, while the middle two panels use the Jorda specification and the bottom two panels use Romer and Romer's (2004) specification. The sample period is 1970 to 1996, the same as the sample period in Romer and Romer (2004). The top panel on the right uses the Romer-Romer shocks as external instruments in Coibion's VAR.

Table 1: Scaled Cumulative Response of Industrial Production
to Monetary Shocks over 36 Months

	VAR Shocks	Romer-Romer Shocks
VAR Specification	1.4	0.7
Jorda Specification	1.0	2.0
Romer-Romer Specification	1.3	3.5

Notes: Each number in the figure is the (negative of the) cumulative response of industrial production divided by the cumulative response of the real interest rate over the first 36 months after a monetary shock.

trates well the point we made earlier in this article that different dynamics of different shocks can make it tricky to apply the estimates from one setting to another without the aid of a model.

5 Conclusion

Macroeconomics and meteorology are similar in certain ways. First, both fields deal with highly complex general equilibrium systems. Second, both field have trouble making long-term predictions. For this reason, considering the evolution of meteorology is helpful for understanding the potential upside of our research in macroeconomics. In the olden days, before the advent of modern science, people spent a lot of time praying to the rain gods and doing other crazy things meant to improve the weather. But as our scientific understanding of the weather has improved, people have spent a lot less time praying to the rain gods and a lot more time watching the weather channel.

Policy discussions about macroeconomics today are, unfortunately, highly influenced by ideology. Politicians, policy makers, and even some academics hold strong views about how macroeconomic policy works that are not based on evidence but rather on faith. The only reason why this sorry state of affairs persists is that our evidence regarding the consequences of different macroeconomic policies is still highly imperfect and open to serious criticism. Despite this, we are hopeful regarding the future of our field. We see that solid empirical knowledge about how the economy works at the macroeconomic level is being uncovered at an increasingly rapid rate. Over time, as we amass a better understanding of how the economy works, there will be less and less scope for belief in “rain gods” in macroeconomics and more and more reliance on solid scientific facts.

The time it will take to drive ideology out of macroeconomic debates depends critically on the quantity and quality of empirical work in macroeconomics. But for good empirical work to

be done in macroeconomics, macroeconomists must take care to train students in the methods needed to do good empirical work. Many of the advances in research design that are currently mainly associated with work in applied microeconomics are highly relevant for developing identified moments in macroeconomics. Understanding these methods and how they are applied within macroeconomics is of great value for macroeconomics students. Likewise, many of the ideas macroeconomists have developed about how to use identified moments to draw inference about policy questions, are also relevant and useful for applied microeconomics.

Table A.1: Romer-Romer Dates and Oil-Shock Dates

Romer and Romer Dates	Oil Shock Dates
October 1947	December 1947
	June 1953
September 1955	June 1956
	February 1957
December 1968	March 1969
	December 1970
April 1974	January 1974
August 1978	March 1978
October 1979	September 1979
	February 1981
	January 1987
December 1988	December 1988
	August 1990

Notes: Romer-Romer dates are dates are identified by [Romer and Romer \(1989\)](#) and [Romer and Romer \(1994\)](#). Oil-shock dates up to 1981 are taken from [Hoover and Perez \(1994\)](#), who refine the narrative identification of these shocks by [Hamilton \(1983\)](#). The last three oil shock dates are from [Romer and Romer \(1994\)](#).

Figure A.1: Response of the CPI and the Nominal Interest Rate to Monetary Shocks

Note: The figure plots the response of the CPI (black line) and the nominal interest rate (blue line) to monetary shocks calculated in six different ways. The light-blue area represents a 95% confidence band for the CPI. The three panels on the left use the monetary shocks produced by Coibion's (2012) monthly VAR, while the three panels on the right use Romer and Romer's (2004) monetary shocks. The top two panels use Coibion's (2012) VAR specification to construct the impulse response, while the middle two panels use the Jorda specification and the bottom two panels use Romer and Romer's (2004) specification. The sample period is 1970 to 1996, the same as the sample period in Romer and Romer (2004). The top panel on the right uses the Romer-Romer shocks as external instruments in Coibion's VAR.
