Diverse Beliefs and Time Variability of Risk Premia

by

Mordecai Kurz, Stanford University
and
Maurizio Motolesi, Catholic University, Milan

March 15, 2009
Defining A Risk Premium on An Asset

• Realized Premium

\[ \pi_{t+1} = \frac{p_{t+1} + D_{t+1} - R_{t}p_{t}}{p_{t}}. \]

Assume: Data available to compute empirical moments

No one knows true probability distributions

• \( m \) = probability implied by the empirical distribution

• All agree on \( m \)

• “The” Premium is the conditional expectations under \( m \)

(1) \[ E_{t}^{m}[\pi_{t+1} | I_{t}] = \frac{1}{p_{t}} E_{t}^{m}[p_{t+1} + D_{t+1} - R_{t}p_{t} | I_{t}] \]

Problem:

What causes the Premium to fluctuate over time?
Some Answers: Macroeconomic Variables

Fama and Bliss (1987) – Internal dynamics of past yields
Campbell and Shiller (1991) – Unexplained shocks to the bond market
Cocharane Piazzesi (2005) – Past yields and Business Cycles
Piazzesi and Swanson (2004) – Recessions forecasts, i.e. Non Farm Payroll..

In empirical finance focus is mostly on predictability of returns by dispersion of earning forecasts e.g. Miller (1977), Diether et al (2002). But also Lee et al (2002), Park (2005), Baker and Wurgler (2006), Campbell and Diebold (2007)

This Paper:
• Effects of diverse beliefs on the risk premium
• Restrictions diverse rationality imposes
• Measuring market belief and testing hypotheses
A Sketch of the Basic Model of Belief

- Risky asset payoff \{D_t, t = 1, 2,\ldots\} with true probability \(\Pi\)
- Non stationary with structural breaks. \(\Pi\) unknown
- True process is Stable:
  - Relative frequencies converge
  - Has empirical distribution
- Substantial past data: all know empirical probability \(m\)

Assume: under \(m\) process is Markov with mean \(\mu\) and transition \(F\)

\[
d_{t+1} = \lambda_d d_t + \rho^d_{t+1}, \quad \rho^d_{t+1} \sim \mathcal{N}(0, \sigma^2_d) \quad \text{where} \quad d_t = D_t - \mu.
\]

- The truth is [I tell you, agents do not know that]
  \[
d_{t+1} = \lambda_d d_t + b_t + \xi^d_{t+1}, \quad \xi^d_{t+1} \sim \mathcal{N}(0, \sigma^2_{\xi}) \quad \text{\(b_t\) sequence of regimes.}
A Sketch of the Basic Model of Belief (cont.)

Note $\Pi \neq m$. **Theorem:** $m$ is stationary and unique

- A belief $Q$ is rational if data generated under it reproduces $m$
- Here: Agents’ beliefs $Q^i$ are Markov

- Disagreement persists:
  Data shows diverse forecasts. Must hold diverse transitions $F^i_t$

Rationality implies (minimally)

(A) A Rational agent cannot hold a constant $F^i_t \neq F$

(B) $F^i_t$ fluctuate over time with $\frac{1}{N} \sum_{t=1}^N (F^i_t - F) \to 0$, for all $i$

[ Diversity and Rationality] $\implies$ Dynamics
Rational Agents are right on average.
A Sketch of the Basic Model of Belief (cont.)
Aim is to manageably describe diversity, not explain it.

**Definition:** A Belief State $g_t^i$ pins down i’s perceived transition of all state variables. In the case of dividend, it takes the form

$$d_{t+1}^i = \lambda_d d_t + \lambda_g^i g_t^i + \rho_t^{id}, \quad \rho_t^{id} \sim N(0, \hat{\sigma}_d^2)$$

- $g_t^i$ is observable since

$$E^i[d_{t+1}^i|I_t, g_t^i] - E^m[d_{t+1}^i|I_t] = \lambda_d^g g_t^i.$$

Assume anonymity: only the distribution is observable.
A Sketch of the Basic Model of Belief (cont.)

In Sum: if rational, \( g_t^i \) must (1) fluctuate, and (2) have a 0 mean.

We represent state of belief with:

\[
(4) \quad g_{t+1}^i = \lambda_Z g_t^i + \lambda_Z^d d_t + \rho_{t+1}^{ig}, \quad \rho_{t+1}^{ig} \sim N(0, \sigma_g^2), \quad \lambda_Z^d > 0
\]

Why:

(I) It is Compatible with the data
(II) Can give an analytic- Bayesian justification.

This also provides an explanation for diversity, if you want it!
Belief Dynamics: A Bayesian Approach

- Two sources: Quantitative $d_t$’s and others $\Psi^i_t$
- Agent believes
- $d_t - \lambda_d d_{t-1} = b_{t-1} + \rho^d_t$ \quad $\rho^d_0 \sim N(0, 1/\beta)$
- At $t-1 (=0)$, a prior distribution on $b_{t-1} \sim N(b, 1/\alpha)$ (d_{t-1} is known)
- At $t$ observe data $d_t$ and update. The posterior on $b_{t-1}$ is

$$E_t^i(b_{t-1} | d_t) = \frac{\alpha b + \beta[ d_t - \lambda_d d_{t-1} ]}{\alpha + \beta}, \quad b_{t-1}(d_t) \sim N[ E_t^i(b_{t-1} | d_t), \frac{1}{\alpha + \beta} ]$$

- At $t$ you forecast $d_{t+1}$ and needs estimate of $b_t$!
- Uses additional sources to assess regime in place
- End up with an alternate estimate of mean value.
- Qualitative information; subjective estimate: $\Psi^i_t$ with uncertainty

$RG_t^i \sim N(\Psi^i_t, \frac{1}{\gamma})$
Belief Dynamics: A Bayesian Approach (cont.)

Assumption: The adjusted posterior distribution at $t$ is then
\[ b_t = \mu b_{t-1}(d_t) + (1 - \mu) R G_t^i \]

Hence we have
\[
E_t^i(b_t|d_t, \Psi_t^i) = \mu E_t^i(b_{t-1}|d_t) + (1 - \mu) \Psi_t^i \quad 0 < \mu < 1
\]
\[
\text{Var}(b_t|d_t, \Psi_t^i) = \left[ \mu^2/\alpha + \beta \right] + \left[ (1 - \mu)^2/\gamma \right]. \quad \text{Let } \zeta = 1/\mu^2, \xi = 1/(1 - \mu)^2
\]

\[
\Gamma(b_t) = \frac{\zeta(\alpha + \beta)\xi\gamma}{\zeta(\alpha + \beta) + \xi\gamma}.
\]

Now observe $d_{t+1}$.
- Followed with (i) a Bayesian update and (ii) a new $\Psi_{t+1}^i$
- Deduce a new prior for $b_{t+1}$ as above

Iterate forward.
Belief Dynamics: A Bayesian Approach (cont.)

**Theorem 1:** The precision of the posterior evolves according to
\[
\Gamma_{t+1} = \frac{\zeta (\Gamma_t + \beta) \xi \gamma}{\zeta (\Gamma_t + \beta) + \xi \gamma}.
\]
It converges to a unique positive bounded solution \( \Gamma \to \Gamma^* \). Defining
\[
g_t^i = E_t^i (b_t | d_t, \Psi_t^i) - \frac{\mu \beta \Gamma^*}{\Gamma^* + \beta} d_t,
\]
then the law of motion of \( g_t^i \) converges to a Markov transition
\[
g_{t+1}^i = \lambda_Z g_t^i + \lambda_d^i d_t + \rho_{t+1}^{ig}
\]
with
\[
\lambda_Z = \frac{\mu \Gamma^*}{\Gamma^* + \beta}, \quad \lambda_d^i = \frac{\mu \beta [\lambda_Z - \lambda_d]}{\Gamma^* + \beta}, \quad \rho_{t+1}^{ig} = (1 - \mu) \Psi_{t+1}^i.
\]
Dynamics of Market Belief

Definition: Market belief is the distribution \((g_t^1, g_t^2, \ldots g_t^N)\) observed by sampling hence with known moments.

- Define: Mean market state of belief is 
  \[ Z_t = \frac{1}{N} \sum_{i=1}^{N} g_t^i \]

- Average (4) 
  \[ \frac{1}{N} \sum_{i=1}^{N} g_{t+1}^i = \lambda_Z \frac{1}{N} \sum_{i=1}^{N} g_t^i + \lambda_d d_t + \frac{1}{N} \sum_{i=1}^{N} \rho_{t+1} \]

- Key condition: \(\rho_{t+1}^i\) are correlated hence 
  \[ \frac{1}{N} \sum_{i=1}^{N} \rho_{t+1}^i = \rho_{\rho_{t+1}} \neq 0. \]

- \(Z_t\) is a state variable with empirical distribution 
  \[ Z_{t+1} = \lambda_Z Z_t + \lambda_d d_t + \rho_{t+1} Z_t \quad , \quad \rho_{t+1} \sim N(0, \sigma_Z^2). \]

**In all models:** this correlation is the crucial factor
The Structure of Beliefs: Perception Models

- We thus expand the empirical distribution to \{ (d_{t+1}, Z_{t+1}) , t = 1,2,... \}.

\[ d_{t+1} = \lambda_d d_t + \rho_{t+1}^d \]
\[ Z_{t+1} = \lambda_Z Z_t + \lambda_d^Z d_t + \rho_{t+1}^Z \]

- Individual i’s perception model (together with (4))

\[ d^i_{t+1} = \lambda_d d_t + \lambda_d^g g^i_t + \rho_{t+1}^{id} \]
\[ Z^i_{t+1} = \lambda_Z Z_t + \lambda_d^Z d_t + \lambda_d^g g^i_t + \rho_{t+1}^{iZ} \]

Parameter sign \( \lambda_d^g \geq 0 \) and \( \lambda_d^Z \geq 0 \) orient the model: When \( g_t^i > 0 \), i believes t+1 dividend and market belief will persist above normal.
An Illustrative Infinite Horizon Model

- Many agents and a single commodity -- “consumption”
- Riskless technology: 1 input at $t$ produces $R > 1$ at $t+1$
- One risky asset with supply $S = 1$
- Risky asset payoff process $\{D_t, t = 1, 2, \ldots\}$ with unknown probability $\Pi$
- Under $\mathbb{m}$ $\{D_t, t = 1, 2, \ldots\}$ is Markov with transition

$$d_{t+1} = \lambda_d d_t + \rho_{t+1}^{d}, \quad \rho_{t+1}^{d} \sim \mathcal{N}(0, \sigma_d^2) \quad \text{where} \quad d_t = D_t - \mu.$$

Notation

- $\theta_t^i = \text{date } t \text{ asset purchases of } i.$
- $B_t^i = \text{date } t \text{ investment of } i \text{ in riskless technology}$
- $p_t = \text{date } t \text{ price of the risky asset. Think of it as the S&P 500}$
An Infinite Horizon Model (Cont.)

(7) \[
\text{Maximize } \max_{(\theta^i, B^i)} E_t \left[ \sum_{k=t}^{\infty} -\beta^{k-1}e^{-(\frac{c_k^i}{\tau})} | I_t \right]
\]

Subject to
(i) \[c^i_t = \theta^i_{t-1} [p_t + d_t + \mu] + B^i_{t-1} R - \theta^i_t p_t - B^i_t,\]
(ii) i’s belief as specified in (6a)-(6b)
(iii) Initial values \((\theta^i_0, B^i_0)\)

Advantage: only mean market belief matters.

State variables in individual optimization:
\[
\psi^i_t = (1, d_t, Z_t, g^i_t) \quad u = (u_0, u_1, u_2, u_3) \text{ constants}
\]
Equilibrium Asset Price and Risk Premium

Stability Conditions:
\[ R = 1 + r > 1 , \quad 0 < \lambda_d < 1 , \quad 0 < R - (\lambda_Z + \lambda_Z^g) < 1 . \]

Theorem 3: There is a unique equilibrium price function of the form
\[ p_t = a_d d_t + a_Z Z_t + P_0 \] with parameters
\[ a_d = \frac{a_Z \lambda_d^d + (\lambda_d + u_1)}{R - \lambda_d} , \quad a_Z = \frac{(a_d + 1) \lambda_d^g + (u_2 + u_3)}{R - (\lambda_Z + \lambda_Z^g)} > 0 \quad P_0 = \frac{(\mu + u_0)}{r} - \frac{\sigma^2}{R \tau} . \]

- Price exhibits “excess” volatility due to beliefs

Now we can compute the premium
\[ E_t^m[\pi_{t+1} | I_t] = \frac{1}{p_t} E_t^m[p_{t+1} + d_{t+1} + \mu - Rp_t | I_t] \]
Structure of the Risk Premium: Main Result

(9) \[ E_t^m[\pi_{t+1}|I_t] = \frac{1}{p_t}[\left(\frac{r\hat{\sigma}_V^2}{\sigma^2_R} - u_1 d_t - u_0\right) - a_Z(R - \lambda_Z)Z_t] \]

**Main Theorem:** Since \( a_Z(R - \lambda_Z) > 0 \), the Risk Premium increases in \( \hat{\sigma}_V^2 \) and falls with mean market belief \( Z_t \). Also,

\[ \hat{\sigma}_V^2 \approx (a_d + 1)^2\hat{\sigma}_d^2 + a_Z^2\hat{\sigma}_Z^2 \]

That is
- In an optimistic market the long position is less risky
- In a pessimistic market the long position is more risky
Effects of Belief on Premium: What Does It Not Say

- Agents are on their demand functions
- It is not “optimal” to be a contrarian
- A “contrarian” may be short when wants to be long and long when wants to be short
- Analogous to why we do not adopt a log utility
Comments

- **With Non-Exponential Utility**: entire distribution \((g_t^1, \ldots, g_t^N)\) matters but **Main Result** holds.

Empirical work considers first two moments:

- Mean market belief \(Z_t = \frac{1}{N} \sum_{i=1}^{N} g_t^i\). Diversity \(\sigma_t^Z = \sqrt{\frac{1}{N} \sum_{i=1}^{N} (g_t^i - Z_t)^2}\)

- Hypothesis: effect of cross sectional diversity \(\sigma_t^Z\) on risk premium is negative (the “Narrow Door Hypothesis”)

Empirical Test of the Main Result

- Dependent variable = realized excess holding returns

- 1 - 6 months holdings of Fed Funds futures and 1 - 12 months for T Bills

- Thus: 30 models.

(1) T Bill and Federal Funds Futures Interest Rate Forecasts:

- Forecast data of interest rates by Blue Chip Financial Forecasts (BLUF)

- Use forecasts of interest rates to construct beliefs as in theory

- Construct \( Z_t^{(k,h)} \) for maturity \( k \) and holding period \( h \)

- Notation: \( Z_t^{(k,h)} > 0 \) means market believes interest rate on maturity \( k \) will be higher than normal at \( t + h \).

- To be beneficial to long position, orientation of \( -Z_t^{(k,h)} \) is as in theory.
Measuring Market Belief Distribution

- For any $X$, we defined
  \[ E^i[X_{t+h} | I_t, g_t^i] - E^m[X_{t+h} | I_t] = \lambda^g g_t^{iX_h} \]

- $E^i[X_{t+h} | I_t, g_t^i]$ is provided in BLUF data, The Problem is $E^m[X_{t+h} | I_t]$
- Stock and Watson’s diffusion indices method explained in paper
- Method uses 215 monthly time series integrated via factor analysis
- Stock and Watson (2002) show the best stationary forecast of $X$ uses a combination of factors and lagged variables of $X$
- Hence, we forecast inflation and interest rates by using the appropriate factors and past inflation and interest rates.

- **Data on realized returns**: CBOT and the familiar Fama Bliss (1987) files, updated to 2003:11 by using Bliss’s program. (see Bliss (1997) for details of the method used).

Estimating Risk Premium Functions

Estimated Function

$$\pi_t^{(X,h)} = \alpha_0^{(X,h)} + \alpha_1^{(X,h)} B_t + \alpha_2^{(X,h)} M_t + \epsilon_t^{(X,h)}$$

$B_t$ = vector of market belief variables

$M_t$ = standard macroeconomic variables [models of Cocharane Piazzesi (2005), Piazzesi and Swanson (2004)]

$B_t$ : Two Moments of the Distribution of Beliefs

- $Z_t^{(k,h)}$ – belief in date t+h interest rate of maturity k at t+h
- $\sigma_t^{(k,h)}$ – cross sectional standard deviation of individual beliefs: + or - ?

$M_t$ : Traditional Variables: Recession, Monetary Policy and Past Yields

- $\text{NFP}_{t-1}$ – year over year growth rate of Non Farm Payroll at t-1
- $\text{CPI}_{t-1}$ – year over year rate of inflation at t-1
- $F_t$ – Federal Funds rate measuring state of monetary policy
- $R_{t-1}^{Fj}$ – principal components of past interest rates $j = 1, 2, 3.$

</table>
Economic Evaluation of the Effects of Belief

JOINT EFFECT: Both belief variables $B_t^{(X,h)} = (\sigma_t^{(X,h)}, Z_t^{(X,h)})$.

- $J_t^{(X,h)} = \hat{\alpha}_2^{(X,h)} \cdot B_t^{(X,h)}$ - belief component is Positive or Negative.

- Look at $|J_t^{(X,h)}|$ with a mean of $\overline{|J^{(X,h)}|}$.

Table 5: Component of Belief in the Premium ( b. points, annualized)

</tbody>
</table>
Economic Evaluation (Cont.)

(1) $|J^{(X,h)}|$ is often larger than 50% of mean premium

(2) $|J^{(X,h)}|$ declines to about 50% at $h=12$

Conclude that

- Risk premia dominated by beliefs for short $h$
- The impact of beliefs declines with duration of holding period
- Pure belief effect accounts for 50% of mean premia for $h = 12$
